period. The destructive changes are (a) resorption atrophy and rarefaction of bone and (b) necrosis of bone and sequestrum formation. The productive changes are (a) new formation of bone and (b) sclerosis of the bone. Passage from the acute to the chronic period is gradual and the latter is characterized by the persistence of fistulas and sequestra which keep up the suppuration.

The onset of acute osteomyelitis may be violent or preceded by a prodromal stage of several days with weakness, loss of appetite, rheumatic pains, or urticarial rash. Local and general symptoms vary in severity from case to case and three clinical forms are recognized: localized hyperacute toxic, and septicopyemic. Under no circumstances should the result of laboratory examinations be awaited before instituting treatment, since more than 90 per cent of the bacteria are penicillin sensitive. When the body has failed to overcome the infection the disease passes into the chronic stage. The following complications were observed in the 65 cases: arthritis in 18 (hip 9, shoulder 2, ankle 1), pathologic fracture in 4 (tibia 3, femur 1), purulent pericarditis in 2, and tibia vara in 1. In the nursing osteomyelitic arthritis of the hip evolves with a characteristic clinical symptomatology: pathologic luxation from destruction of the femoral head is the rule and can often be corrected only by a reconstructive operation.

The earliest roentgen signs appear from the seventh to the tenth day but sometimes only between the fifteenth and twentieth days and from the fourth or fifth day in nurslings. Small irregular zones of reduced density appear in the bone and, while spreading, assume a porous moth-eaten speckled aspect because of decalcification, resorption and destruction of the trabeculae and thinning or perforation of the cortex. In the second or third week subperiosteal new bone is formed, always less dense than that of the cortex. In chronic osteomyelitis the necrosed bone is denser than the neighboring bone after 3 to 6 weeks and a line of demarcation appears between the living and dead bone. The sequestrum is usually surrounded by a clearer halo.

Treatment may be general or local; the general type consists of chemotherapy with penicillin, sulfonamides or streptomycin, hydration, alimentation and transfusions; the local type of immobilization, surgical interventions and local chemotherapy with penicillin or streptomycin. The two most urgent considerations are the administration of penicillin and immobilization. To be efficacious penicillin treatment must be started early with adequate dosage and continued without interruption for a sufficient time. The author uses an aqueous solution of sodium penicillin intramuscularly in the following dosage: from 20,000 to 30,000 units every 3 hours in children below the age of 2 years; from 30,000 to 100,000 units every 2 to 3 hours in older and adolescent children. The daily dose may also be calculated from the weight of the child: from 20,000 to 30,000 units per kilogram. The treatment generally takes 3 to 4 or more weeks and the dosage is reduced

gradually as improvement becomes evident. Immobilization must be instituted as soon as the diagnosis is suspected, and must be maintained until the bone shows satisfactory resistance. The treatment of acute recurrence in chronic osteomyelitis is the same as that for acute osteomyelitis.

In the radical treatment of chronic osteomyelitis penicillin is started from 2 to 4 or more days before intervention which will consist of curettage, sequestrectomy and canalization (saucerization) or subperiosteal diaphysectomy according to the case. The ideal procedure is then to cover the open bone with a thick layer of soft tissue and to close the skin without drainage. A Nélaton sound is introduced through a small counter opening to instill penicillin. In extensive loss of soft tissues a plastic procedure may be necessary. Residual bone cavities are filled with bone chips and covered with a pedicled skin graft.

With penicillin treatment the mortality of acute osteomyelitis has fallen to from 0 to 15 per cent. In the 35 acute cases of the present series there has been no fatality. Although it is too early to speak about permanent cure, healing was obtained in more than half of the cases when penicillin treatment could be started between the first and fifteenth days of the disease; the average treatment starting before 6 days. The cases which were admitted between the seventh and thirtieth days (average of 15.6 days) became chronic. In 16 of 29 controlled cases it was necessary to incise a subperiosteal or soft tissue abscess; hospitalization ranged from 8 to 90 days with an average of 33.17 days. In chronic osteomyelitis it is even more difficult to evaluate results, however they were frankly encouraging, especially in cases in which bone grafts were used.

The evolution and duration of the disease in the nursing are shorter because of the greater speed of the processes of resorption and reconstruction of the bone; the average duration is 2 months. In general the septicemic symptoms predominate over the bone symptoms; however a septicemic and a pure osteomyelitic form can be distinguished. With penicillin therapy there was no fatality among the 13 cases observed. The prognosis for the bone lesion is good as healing is usually rapid, complete and final. However, if the joint or the growth cartilage has been involved, shortening of the extremity, changes in the growth of the axis (genu valgus or varus) and pathologic luxation may occur. RICHARD KEMEL, M.D.

Applied Muscular Physiology in the Healing and Treatment of Fractures (Angewandte Muskelphysiologie beim Knochenbruch seiner Heilung und Behandlung) E. REHN *Chirurg* 1946 17:18-14.

The author believes that both clinical observation and experimental evidence suggest that the muscles play an important role in the healing of fractures. The primary process in the formation of callus has been thought to be hyperemia in the area of the fracture. Rehn however believes that this hyper-

mia is of only transient appearance and usually disappears in about a week. On the other hand the status of the muscles surrounding the fracture their irritability and their other physiological responses closely parallel the healing of the fracture.

Immediately or soon after the fracture has occurred there is a lack of response in the muscles of the injured area which the author calls muscle torpor. After a week, however the muscle displays increased irritability, which he terms intermittent tetanus. It is in this stage that the callus is deposited. The muscle furthermore acts as a guide to the correct reposition of the fractured bone ends. Therefore it serves a useful purpose and only occasionally does its interposition between the fragments cause difficulty.

For this reason the muscle should be treated with respect. Severe distraction will soon cause muscular relaxation and the muscle is then incapable of performing its useful function.

The original muscle torpor is valuable in that it permits the influx of the capillaries of the granulation tissue and the deposition of lime salts. Then the return of the muscle hyperirritability permits the laying down of useful callus. As an example of this it will be noted that the so-called march fractures which occur in areas which are not covered with muscles heal poorly with much callus and pseudarthrosis. The best healing is obtained after accurate reposition of the fragments in areas where the muscles run parallel to the bone fragments.

WILLIAM C. BLACK, M.D.

Experimental Degeneration of the Supraspinatus Tendon CHARLES LAIRD WILSON. *J Bone Surg* 9:2, 30-A. 766.

The pathology of rupture and degeneration of the supraspinatus tendon in human beings has been described in a previous publication. It has been shown that a characteristic type of degeneration precedes and leads to rupture of the tendon. There has been much speculation concerning the cause of this syndrome. The purpose of this article is to describe the experimental production of these pathological changes in the supraspinatus tendons of rabbits.

The supraspinatus tendon was traumatized in 46 rabbit shoulders. These tendons were examined at intervals varying from 42 to 111 days. When the shoulders were re-opened for biopsy only 5 of the subdeltoid bursae had a normal appearance. 19 showed fine adhesions. 17 showed dense adhesions and 5 were completely obliterated.

Some of the evidence of tendon degeneration observed in either partially or completely ruptured human supraspinatus tendons was reproduced in the supraspinatus tendons of rabbits by a single trauma. The microscopic evidence of tendon degeneration was a loss of the normal wavy configuration of the collagen bundles, the homogeneous appearance of the tendon, a change in the character of the staining properties, an increase in the number of blood vessels observed and the loose edematous, fibrillated

appearance of the degenerated tendons. This fibrillation was not so marked as that observed in human tendons which had ruptured.

Of the 46 tendons 87 per cent showed a loss of the normal wavy configuration of the collagen bundles and instead had a homogeneous appearance, 39 per cent showed early fibrillation and 48 per cent showed an increase in the number of blood vessels supplying the tendon.

It is concluded that the degeneration observed in the human supraspinatus tendon is caused by trauma incurred during the life of an individual.

RUDOLPH S. REICH, M.D.

The Surgical Concept and Treatment of Supraspinatus Tendinitis (Concepto y tratamiento quirúrgico de la tendinitis del supraspinoso). R. PAEL DE VERA y FERNANDO DE ANDRÉS. *Rev Asoc Cir* 9:17 109.

The pathologic anatomy of supraspinatus tendinitis is divided into primary tendinitis or that in which the degeneration changes are ultramicroscopic but in which necrosis of the soft parts is present, and the local metabolism and biochemistry are altered. However there is no calcification but if the condition is not arrested calcification will invariably occur. The second type is calcified tendinitis in which the degeneration has progressed and deposits of one or more calcareous bodies are observed—the latter may occur in as high as 5 per cent of the cases.

Pain and loss of function are the predominant symptoms which together with roentgen views of the shoulder reveal the diagnosis.

The medical aspects of therapy are similar to those of all rheumatoid dyscrasias. Special knowledge of the surgical anatomy and mechanics of the shoulder joint, however is needed for the proper surgical handling of supraspinatus tendinitis. Operation is directed at restoring the dimension of the acromion-humeral space, the elimination of deposits, and the return of the full range of articular motion. To accomplish this, resection of the acromion process may be required and the technique for its extirpation is given in detail. A modified Watson-Jones procedure is employed by the authors.

Discussion of Physiopathology of the Paw in Volkmann's Disease: Experimental Study of Contracture Provoked by the Intra-Arterial Injection of an Organic Iodine Product (Réflexions sur la physiopathologie de la griffe dans le malade de Volkmann. Etude expérimentale des contractures provoquées par l'injection intra-artérielle d'un produit iodo-organique). R. FORTALIER, CH. KATZ, CH. MARX, and A. DANT. *Lyon chir* 9:2, 43-499.

While the etiology of Volkmann's contracture is now definitely known, being the result of an arterial lesion, the mechanism of the condition still remains obscure. The fact that ligation of the brachial artery is usually well tolerated minimizes the importance of ischemia. Some writers expressed the opinion that a

reflex originating at the point of injury provokes a spasm of arterioles in the muscles and a dilatation of the capillaries and venules. The resulting peripheral stasis leads to necrosis of the muscle tissue. This hypothesis obviously attributes the main rôle to trauma of the blood vessels similar to the first mentioned theory. The third theory maintains that trauma of the nerves either direct by osseous fragments or by insufficient blood supply and cicatricial tissues is of paramount importance.

There is no doubt that a relatively slowly developing contracture is attributable to an injury of the blood vessels but a rapid development of Volkmann's syndrome is more difficult to explain.

An accidental injection of an organic iodine product into the brachial artery which produced at once an arterial spasm and concurrently also a Volkmann's contracture suggested to the authors the following experiments. A few cubic centimeters of an iodine product called tenebryl and used for intravenous pyelography were injected into the brachial arteries of dogs. A marked contracture developed after 3 to 10 seconds and was accompanied by severe pain and lack of the peripheral pulse. The contractures were registered by means of electromyography. They immediately reached the maximum height and decreased progressively within from 14 to 30 minutes. Direct compression of the brachial artery did not produce a contracture however immediately following the removal of the tourniquet as soon as the injected product could reach the periphery a contracture occurred.

After the section of all the nerve trunks the first intra-arterial injection of tenebryl produced a contracture of a short duration but a second injection had no effect.

A passive extension of the paw during the decline of the contracture provoked by an injection of tenebryl caused an instantaneous intensification of the contracture.

The following conclusions are drawn by the authors from their experiments. Contractures pro-

duced by injections of the iodine product depend on a certain mechanism in the central nervous system as shown by the fact that the section of the peripheral nerves reduces greatly the intensity of the spasm and renders the repetition of the phenomenon impossible. The observation that a passive extension of the paw during the decreasing phase of the contracture intensifies the latter explains some bad results of the treatment of Volkmann's disease by early extension of the flexed fingers.

Voluminous Myeloplaxic Tumors of the Tendon Sheaths of the Ankle with Secondary Osseous Lesions (Volumineuses tumeurs à myélopaxies des gaines tendineuses du cou-de-pied avec lésions osseuses secondaires) F. CARY *Mém Acad chir* Par 1948 74 549.

A young woman consulted the author because of a deformity and pain in the left lower extremity of 10 years duration. Nine years prior to the examination a fusiform shadow in the roentgenogram was found between the tibia, os calcis and the Achilles tendon. Gradually the tumors increased in size and in 1942 osseous alterations were detected in the form of erosions in both malleoli, the scaphoid, astragalus and os calcis of the involved extremity.

The examination revealed numerous round tumors surrounding the involved ankle. The foot was kept in an equinus position. The tumors of soft consistency were immobile but not adherent to the skin. There were no adenopathies.

An amputation was performed through the lower third of the lower leg. The patient made an uneventful recovery.

The histologic examination revealed myeloplaxic tumors of pseudoxanthomatous character. The tumors were attached to the peritendinous tissues and their vascularization appeared to be of an osseous origin. Apparently the tumors developed not from the synovia of the tendons but from osteofibrous sheaths.

Phlebography in the Localization of Incompetent Communicating Veins in Patients with Varicose Veins. THEODORE B. MASSELL AND JEROME ETTINGER. *A Surg* 1948, 18:1:17

The late results of varicose vein treatment by high saphenous vein ligation are unsatisfactory because of the presence of incompetent at communicating veins detected by tourniquet examination. A phlebographic technique for detection of incompetent perforators is described whereby three tourniquets are placed, respectively just above the malleoli just above the femoral condyles and as high as possible on the thigh. Diodrast is injected into a superficial vein on the dorsum of the foot and films are taken. The tourniquet above the malleoli blocks the superficial venous channels and forces the injected material into the deep veins. If the deep channels are free of obstruction the diodrast does not return to the superficial veins. The two tourniquets on the thigh however provide enough obstruction to the normal flow to cause the diodrast to pass retrogradely through incompetent perforators to the superficial system.

Twenty cases are described in which preoperative localization by tourniquet tests and phlebograms was carried out and operation was then done to verify or disprove the preoperative data and test the comparative accuracy of the two methods. Neither the tourniquet examination nor phlebography correlates completely with the operative findings. Fifty-four per cent of the incompetent veins localized by tourniquet were confirmed by surgery where as 86 per cent localized by phlebography were confirmed. Also incompetent veins not detected by tourniquet or phlebography were found at operation which made the over-all localization accuracy of tourniquet tests 59 per cent and that of phlebography 69 per cent.

Actually the operative findings are not always completely accurate. The anterior tibial veins appear to be the most difficult to be visualized roentgenologically and at times the posterior tibial veins are not completely filled. Visualization of the peroneal veins is almost always excellent. Improvements in roentgen-ray technique and experience in interpretation will probably increase the accuracy of phlebography in localizing incompetent communicating veins. JAMES E. THOMPSON M.D.

Wounds of Common Carotid Arteries. Report of 17 Cases from World War II. KNOWLES B. LAWRENCE, LAWRENCE M. SAKETS, and JOHN R. MCDANIEL. *Am J Surg* 1948, 76:59.

A series of 17 wounds involving the common carotid artery occurring during World War II is reported. Excluding 1 case the average recorded time lag from

wounding to surgery was 11 6 hours. The artery was ligated in 13 instances with the survival of 8 patients and transient hemiplegia in 2. Of the 5 patients in whom ligation was not done 4 died 2 from arterial occlusion by a thrombus, 1 because of a subcutaneous hemorrhage from a severed vertebral artery, and 1 following arterial anastomosis by the Bilemore method.

Early wound débridement and direct attack on the arterial defect was preferred in these injuries of the common carotid artery. Immediate ligation is highly hazardous. The extent and spread of the thrombus in the arterial tree and the quality of the pre-existing collateral circulation are the two most important factors in the eventual prognosis, and both are unpredictable clinically. The mortality rate in this series was 47 per cent.

Recent improvements in surgical methods for restoring blood vessel continuity notably by rapid temporary canalization may reduce the mortality rate and should be employed whenever possible. However the unavoidable time lag before surgery and the inherent inadequacies of the cerebral collateral circulation shown by many individuals will probably maintain the mortality rate at a high level.

ROBERT A. NARATOFF M.D.

Experimental Studies in Vascular Repair. Comparison of Reliability of Various Methods of End-to-End Arterial Sutures. HARRIS B. SAMMICKER, JR., and ROBERT I. LOWENBERG. *Surgery* 1948, 24:79.

Since the relative worth of various techniques can be determined by controlled experiments performed upon one artery on one species of animal by the same group of workers, the authors, using the common carotid arteries of dogs compared the reliability of four types of end-to-end repair. Interrupted plain, continuous plain, continuous mattress, and interrupted everting mattress sutures. Neither techniques involving nonpenetration of the intima nor nonsuture methods were studied. Anticoagulants were not administered.

From these studies it appeared that mattress sutures which fix the opposed ends of the vessel in a position of eversion are superior to plain sutures which bring the ends of the vessel together layer to layer. The superiority of the mattress technique is most evident with regard to the avoidance of such complications as dehiscence, aneurysm, and stricture there was no significant difference between plain or mattress sutures with regard to the incidence of thrombosis. Also, less bleeding was noted when mattress sutures were used. It also was apparent, although the series was too small for significant analysis, that the chance of success in arterial suture is definitely reduced when one is working with a vessel of extremely small size. No significant difference was

noted between the use of continuous and interrupted suture methods.

Regardless of the method of suture certain fundamental principles must be followed to obtain good results

- 1 The loose external adventitia must be stripped so that adventitia does not fall into the suture line.
- 2 The vessel must be handled gently
- 3 The vessel must not be allowed to become dry
4. Only fine needles and fine nonabsorbable suture materials should be employed and these should be kept moistened with mineral oil or saline solution.
- 5 The vessel wall should be approximated with the intimal layer everted.
- 6 Infection must be avoided

EDWARD H. CAMP, M.D.

Experimental Portacaval Anastomosis. RICHARD E. GARDNER, FRANK H. LEEDS and NORMAN E. FREEMAN *California M.*, 1948 69 1

The authors performed an anastomosis of the end of the portal vein to the side of the inferior vena cava in 15 dogs. The operative exposure was modified in the last 9 cases to a right thoracoabdominal incision which extended along the tenth interspace and divided the diaphragm laterally and posteriorly to the attachment of the liver. The hepatorenal ligament

was cut and the kidney pushed down. The anterolateral surface of the inferior vena cava was dissected free from the entrance of the renal vein to the point where it passed beneath the liver. Dissection of the portal vein from the superior mesenteric vein to its bifurcation at the hilus of the liver was then done. The vena cava was then partially occluded by a modified kidney pedicle clamp and incised longitudinally on its anterolateral aspect for anastomosis to the divided portal vein. Deknatel ooooo and a curved atraumatic needle were used to place everting mattress sutures at each end and the anastomosis was completed with a continuous anterior posterior suture, tied to the everting mattress sutures. The animals were sacrificed at intervals of from 1 day to 4 months postoperatively. There was thrombosis in one instance which they ascribed to some angulation of the portal vein.

This method was used in one patient with portal cirrhosis in whom the approach was modified by entering the ninth instead of the tenth interspace. The patient expired on the fifth postoperative day from hepatorenal failure. At autopsy the anastomosis was patent. The use of a left thoracoabdominal approach for splenorenal anastomosis in clinically doubtful cases is suggested.

LEROY J. KLEINHAUSER, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Further Studies on the Anticoagulants. CARL REICH and WILLIAM EISENBERG. *Am J M Sc* 948, 5 67

This report embodies a continuation of studies on dicumarol and heparin initiated at Lenox Hill Hospital, New York, New York in 1943. Since that time these anticoagulants have been under constant observation at this institution. They have been used both for the prevention and the treatment of thrombotic conditions. Favorable results have been described in previous communications.

The present series of cases including approximately 300 patients can be divided into 4 main groups: (1) postoperative cases in which treatment was given prophylactically with anticoagulants to prevent thrombotic conditions; (2) cases of active venous thrombosis; (3) acute embolic episodes, usually pulmonary; and (4) cases of coronary thrombosis.

Postoperative venous thrombosis and pulmonary embolism can definitely be prevented in all cases by the prophylactic use of anticoagulants.

The treatment of established thrombotic conditions by means of anticoagulants is effective and safe.

In coronary artery disease the main value of the anticoagulants is the prevention of complicating embolism.

The details of the use of heparin and dicumarol are outlined in full. The authors' wide experience is also given in detail.

HARRY W. FINE, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

The Control of Infection in Burns. LEONARD COLE, BROOK, J. M. DUNCAN and W. P. DALLAS ROSE. *Lancet Lond.* 948, 1 893.

This is the second report on the control of infection in burns at the Birmingham Accident Hospital in England. Since 1935 a serious attempt has been made to treat burns under conditions which aim at eliminating not only infections from contact (hands, instruments) but also airborne infections.

The term "infection" is used throughout in a bacteriological rather than a clinical sense. The term "added infection" connotes the recovery of one of the three "indicator organisms," that is, hemolytic *Streptococcus* (Group A) *Pseudomonas pyocyanea*, or *Bacillus proteus*, if these organisms were not found on any of the patient's burned areas on admission. It is the equivalent of "acquired in the hospital."

The method of treatment of the burned surfaces was essentially the same throughout the three year period. Briefly the wounds were cleaned and penicillin cream was applied. Great care was taken to obtain perfect coverage of the burns, and skin replace-

ment was carried out for the deeply burned areas at an early stage. Penicillin and the sulfonamides were seldom given systemically. Dressings were applied by a team using strict aseptic precautions. All dressings but the first were applied in a special room continuously supplied with an abundant stream of twice filtered and warmed air which escaped by a single exit. An interval of 5 minutes was allowed between dressings for re-cleaning the air. Cultures were taken on admission and at each subsequent dressing.

The outstanding feature of this experience was that it has been possible to eliminate almost completely clinically manifest infections from the *Bacillus hemolytic streptococcus* (Group A) and to reduce the "silent" infections to very few. Only 3.9 per cent (39) of the patients already had an infection from this bacterium on admission but none were seriously ill. The streptococci were eliminated within a few days by the local application of penicillin cream at 2-day intervals. Thirty-eight, or 5.4 per cent, of the patients acquired an infection of this kind during their hospital stay but in no instance was there an infection of the invasive type. In only 14 patients did the *Streptococcus* appear within the first 2 weeks. On the few occasions when streptococci were present on a wound at the time of skin grafting the "take" was poor or nil.

Only 1.8 per cent (13) of the patients had *Pseudomonas pyocyanea* on admission and none of these was admitted early after the burn. However 8 per cent (60) acquired the organism in the hospital. In all but 3 cases transmission of the infection took place in the wards between dressings and there was a close correlation between these added infections and imperfect covering of the wounds. There is much to be learned about the spread of this infection. This organism has never been cultured from the throat or nose swabs of either staff or patients. It appears that the dissemination is by dust and probably flies. However as Neal Owens has pointed out, the imperfectly applied burn dressing may become soaked with serous fluid and be transformed into a mass of culture medium through which pathogens conveyed to the outer bandages will readily grow and infect the underlying wound. A sheet of cellophane incorporated in the dressing serves as an effective barrier.

The usual local applications of antibiotics reported to be efficacious against these organisms have failed. The *Pseudomonas pyocyanea* readily acquires a resistance to streptomycin in the form of a cream. Fortunately not much harm has resulted from the infections, and skin grafting and healing of the wounds has been little affected. However there were 3 cases in which the results were almost disastrous and which reaffirm the urgent need for a therapeutic agent which will eliminate *pyocyanea* infection from burns as rapidly as penicillin does in the case of the hemolytic *Streptococcus*.

Only 0.8 per cent (6) of the patients had *Bacillus proteus* on their burns on admission while 12 per cent (89) acquired it during their hospitalization. All attempts to eliminate this organism by local application have failed but the organism disappeared as the burns healed.

The *Staphylococcus* has been the most frequent invader of the burns. Only 3 per cent of the patients had this organism on admission but in the more severe cases from 60 to 70 per cent of the patients acquired it at some period of their stay in the hospital. The source of this infection is not clear. In 20 per cent of the patients the organism was recovered from nasal swabs, and during the hospital stay this percentage increased to about 50 per cent. The presence of the *Staphylococcus* in the early stages was associated with slight suppuration and with little or no fever. In a few cases, but not always, the presence of staphylococci on a burn interfered with the successful take of skin grafts. The *Staphylococcus* quickly becomes resistant to local penicillin and especially to local cream applications of penicillin and sulfathiazole.

Infection from *Bacillus tetani* has not occurred in any case and therefore no antitetanic serum has been given.

The great majority of burns which became infected at some period of hospitalization had no pathogens on admission; therefore most of the infections were acquired in the hospital. At least 90 per cent of the infections were due to transmission not at the time of dressing in the specially designed dressing rooms but between one dressing and the next. The transmission took place in the wards and it was clearly associated with imperfect coverage of the wound in most of the cases.

In a few cases serological identity of the streptococcus proved it to have been derived from the patient's own skin or respiratory tract. In the great majority of cases there was no such autochthonous origin and the transmission of pathogens occurred by indirect contact from another infected case or by airborne particles.

This study has made it clear that the majority of these injuries can be kept free from any infection that is clinically significant if the proper conditions are provided. Such provision will involve considerable effort and expense. The questions arise: how much does infection really matter? and is all this effort and expense justified?

The clinical picture of the infected severe burn is all too familiar to most surgeons. The antibiotics have improved this picture to some extent yet the factor of sepsis remains substantially true for most severe burns. Certainly the clinical course of the severely burned patient who does not become infected presents a striking contrast. Such a great change in the clinical course is reflected in the mortality and the period of incapacity.

It is estimated that there are nearly 25,000 burned patients admitted to hospital beds each year in England and Wales. On the assumption that if they

become infected they occupy these beds 10 days longer than uninfected patients it would mean a saving of 250,000 hospital bed days each year. The saving of life and pain and the recovery of full function and the economy of man power and hospital facilities add up to the conclusion that the avoidance of infection in burned patients is the central problem after the management of the shock period.

If that conclusion is valid it means a complete reorientation of our thinking and teaching about burns—we must definitely take as our target the complete elimination of septic infection just as we do for operative surgery. Such a program requires a four fold attack.

1. No pathogens must be allowed to reach the wound at the time of dressing. This means the prevention of transmission from the respiratory tract, instruments, dressings and the air of the room. The use of a specially ventilated room is desirable.

2. No pathogens must be allowed to reach the wounds between one dressing and another. This is a matter of greater difficulty and probably will always be so because burned patients are more easily infected and more infective than any other class of patient. It is far from simple to protect a burn with a proper dressing which offers an effective barrier to bacterial invasion. Even an intact dressing will not afford effective protection when it is soaked with serum for pathogens can grow through it from the outside. Aside from an effective dressing it has been clearly shown that single-bedded cubicles afford the best safeguard against cross infection.

3. The prompt elimination of pathogens from the wounds of those who do become infected is the next objective. By virtue of the power of the antibiotics to control streptococcal infections these infections are now the easiest to control. If we knew how to eliminate the *Pseudomonas pyocyanea* and staphylococcal infections equally promptly certainly the management of a ward full of burned patients would become much easier.

4. The number of raw surfaces must be reduced as much as possible by early and if necessary repeated skin grafting. Yet, however much we improve the set-up for burned patients by nursing in cubicles dressing in microbe-free air and the prompt elimination of pathogens it will never be easy to keep a large raw surface free from infection. The opportunities for such infection will always be numerous and the danger is only past when the raw surface is covered with skin.

There remains for discussion the problem of the influence of administrative management on the control of infection in burned patients. Few hospitals make special provisions for these injuries and the system adopted heretofore of admitting them into general wards of all hospitals cannot be regarded as satisfactory. The treatment is left for the most part to an inexperienced house surgeon. Skin grafting is often not done or is postponed until all sloughs have separated (after 4 to 6 weeks) when the optimal conditions for a successful take no longer exist.

Such arrangements do not offer the burned patients the best or even a good chance of recovery without infection, or recovery with full function.

HARVEY S. ALLER, M.D.

Numerous Tetanus Cases During the Last Phase of the War and Their Treatment with Anatoxin-Formol Toxoid (Über gehäufte Tetanus-Erkrankungen in der letzten Phase des Krieges und über die Behandlung des Tetanus mit Anatoxin-Formol-Toxoid) H. KUTTERN *Chir.* 947 7-8 137

While in Germany the opinion prevailed that a passive immunization against tetanus provides sufficient protection other countries accepted the method of active immunization. The fact that the passive immunization lasts only from 12 to 14 days was sometimes overlooked in patients with several injuries sustained at short intervals and in such instances tetanus occasionally occurred.

Suddenly in 1914 during the battles in the north west region of France the frequent development of tetanus was noticed and in each instance the condition took a grave course. The geographic conditions, intensification of the virulence peculiarity of the injuries and the diminished activity of the prophylactic treatment were considered responsible factors.

The author calls attention to the fact that in Normandy it is customary to employ manure as fertilizer. He is inclined to believe that for unknown reasons the virulence of the tetanus bacilli increased. The kind of missiles was responsible for the increased destruction of tissues. Many wood splinters from collapsing houses were found in the wounds and they favored the tetanus infection. A check-up showed that no serum injected was older than 3 years.

The author calls attention to the fact that in all tetanus cases a prophylactic injection had been given that the incubation period was long, and yet the course of the disease was very grave.

The author considers intravenous serum injections as dangerous especially because an allergy created by previous serum administration may be expected in a large percentage of cases. He also considers doses larger than 50,000 units per day as excessive.

Many surgeons prefer avertin to other sedatives but autopsies repeatedly show a fatty degeneration of parenchymatous organs attributable to that drug. Therefore the author prefers the administration of different sedatives each day.

In view of the fact that none of the war prisoners in whom an active immunization had been employed developed tetanus, the author concludes that this method is superior to passive immunization. The danger of shock from serum is also eliminated when active immunization is employed.

JOSEPH K. KARAT, M.D.

Lat. Tetanus (Spættetanus). HANNO-HEINZ FISCHER. *Chirurg.* 947 17-18 631

A 34 year old patient was operated on for peptic ulcer in January 1916. Stomach resection and gas

troenterostomy were performed and uneventful recovery took place. Five weeks after surgery the day on which the patient was to be discharged, infarction was found in the left upper lobe of the lung with elevated temperature and bloody sputum. Seven days after this episode there were pains in the jaw and in the chest, and on the next day there was trismus and typical tetanus. Only at this time did the patient mention that he was wounded by a rifle shot in the left upper part of the chest in November 1912. A fine scar in the left third intercostal space was present which had been overlooked before. The patient expired a days later in spite of 100,000 units of antitoxin given intravenously and intramuscularly. No autopsy was performed.

This case is typical for late tetanus. Spores deposited at the time of the first injury may survive for many years and be mobilized by subsequent injury operation or other trauma. The tetanus bacillus is anaerobic. Secondary infections with aerobic bacilli which absorb the oxygen in the tissues create optimal conditions for the development of the spores. In the present case the spores were mobilized by a postoperative lung infarction more than 3 years after the original injury. The extremely rapid course of the disease is characteristic for tetanus of the upper respiratory tract.

In connection with this case the author discusses the question of tetanus of other pathogenesis after abdominal surgery. Tetanus bacilli are found frequently as saprophytes in the stools of normal persons (between 5 and 40 per cent, according to different statistics). The possibility of tetanus infection in operations in which the field is exposed to contamination by fecal matter cannot be ruled out entirely and some authors advise preoperative prophylactic antitoxin in such cases.

WERNER M. SCHMIDT, M.D.

Present Day Tendencies in the Treatment of Gas Gangrene (Indirizzi odierni nella cura della gangrena gassosa). LEONARDO GUL. *Chir. org. intern.* 948, 31: 67

In 34 of 45 cases of gas gangrene amputation proved necessary. There were 26 amputations of the thigh, 5 of the leg and 3 of the arm. There were two extractions of the hip joint. In the remaining 9 patients the treatment was limited to local exposure of the wound trajectories with thorough debridement. The wound edges were either cut down to form a broad depression for the wound or turned back to form a flat surface and no suturing was done. In 4 of these 9 cases demolition procedures could not be instituted because of the location of the wound. In 1 instance the wound was situated in the scapular region and in 3 in the region of the buttocks. In the remaining 5 patients local treatment was judged sufficient because of the localized character of the gangrenous process and because it showed little tendency to spread. In 3 of these 5 instances the wound was in the region of the foot, and in 2 in the region of the leg. Eventually one of these patients with

involvement of the foot had to undergo a leg amputation and 1 with a leg wound had to have an amputation at the thigh.

The total mortality in these 45 cases was 15 (30 per cent). This figure compares favorably with those of World War I but is not as good as those of the allied armies of World War II. The latter however had the benefit of penicillin. Despite the fact that the sulfonamides show considerable activity against the organisms which cause gas gangrene infections treated with these drugs seemed to be just as serious as those treated before the sulfonamides were available. This is true particularly of the oral administration of these drugs. However when used locally in combination with the local and general application of penicillin the association does not seem to be antagonistic and may perhaps be synergistic.

Much may be expected of penicillin not only in the matter of prophylaxis but also in the control of the infection itself. In 2 of the author's patients the use of penicillin enabled the amputation which was adjudged necessary not because of the infective process but because of the circulatory conditions present to be done through tissues which must be assumed to have been infected and thus a useful stump was procured. This certainly could not be attempted before the advent of penicillin.

Of course penicillin or any combination of penicillin the sulfonamides and anti-gas-gangrene serum cannot substitute for delay in getting these war wounds under treatment or for the absence of an adequate force of properly trained surgical personnel. The wound must be adequately exposed foreign bodies must be removed and the wound must be watched for the earliest signs of gas bacillus infection.

In conclusion the author warns that although gas gangrene is characteristically a complication of fresh wounds it may develop at re-intervention months or even years after the original injury, as happened in 2 of the author's cases. This eventuality is particularly apt to be met with in the cases of healed open fractures. JOHN W. BRENNAN, M.D.

ANESTHESIA

The Anesthetic Management of Patients with Fracture of the Mandible. S. G. HIZASHY and E. A. ROVENSTINE. *Anesthesiology* 1948, 9, 351.

This is a report of the evolution of an anesthetic technique for operations specifically limited to the fractured mandible without serious involvement of the soft tissues. While the surgical results are not included here they have steadily improved and permitted the oral surgeons to plan a definite approach to a difficult problem. There were no deaths and no serious sequelae relative to respiratory obstruction and aspiration.

Two precautions merit particular mention. Delirium after anesthesia can quickly defeat the entire purpose of the operation by disrupting the reduction and fixation of the fracture. For several years it has been observed that subcutaneous doses of apomorphine are

almost invariably effective in overcoming this complication. The other precaution applies to those instances in which the jaws are to be wired to each other. Aspiration and suffocation resulting from postoperative vomiting are real hazards. It is routine practice to maintain the jaws fixed to each other with rubber bands instead of wire for a sufficient period of time postoperatively so that this accident may be avoided should vomiting occur.

The observations peculiar to the chronic alcoholic patient have been noted as have other lesions of significant value. Of most benefit has been the attitude that the method was still tentative and in need of revision. This produced a variety of solutions for each aspect of the problem and helped to create a technical versatility in managing the individual patient. MARY FRANCES POT, M.D.

SURGICAL INSTRUMENTS AND APPARATUS

A New Material for Surgical Sutures and Ligatures. Igamid B (Ein neuartiges chirurgisches Naeh- und Unterbindungsmaterial Igamid B) L. SNOW. *Chirurg* 1947, 17, 18, 673.

The materials mostly used for surgical sutures catgut, silk, and linen present a number of disadvantages. Catgut is usually sterilized in formalin or tincture of iodine. However only the surface can be sterilized with certainty by these procedures and spores or cocci may survive in the interior of the thread especially if larger sizes are used. This fact accounts for the occurrence of late infections and suppurations when the catgut is in the process of resorption and the interior layers are exposed.

Silk and linen can be sterilized more safely by boiling in 1 per cent mercuric chloride solution however frequent boiling decreases the resistance against tearing.

During the war I. G. Farben in Germany developed a synthetic substance called igamid B which proved to be very useful for surgical suturing. Chemically it is closely related to nylon. As it is manufactured at a temperature of 300°C it is absolutely sterile. Its further advantages are that its resistance against tearing is extremely high about the same as steel so that much thinner threads can be used than with catgut or silk. Threads of any diameter can be produced. It does not swell by imbibing tissue moisture. It can be stretched about 15 to 20 per cent and is completely elastic. It can be sterilized by boiling any number of times without losing its original physical properties. It does not cause any local irritation.

The only disadvantage seems to be that the surface is very hard and smooth. This necessitates a special technique in tying knots to prevent slipping. Experiments with braided threads are under way to overcome this difficulty.

Also other surgical instruments have been made from this material sheets to close defects in the abdominal wall in large abdominal hernias bone hammer bone nails and wires.

WERNER M. SOLMITZ, M.D.

Supramid a New Synthetic Substance in Surgery
 (Supramid—ein neuer Kunststoff in der Chirurgie)
 F. LINDER and M. SCHWABER. *Chirurg* 1947
 17: 8, 675.

Supramid is identical with Igarid B which has been described by L. Simon. This article confirms the facts reported by Simon. Chemically supramid is a so-called superpolyamid and it is closely related to nylon. Its physical properties are

Specific weight $\times 13$

Resistance against bending kgm./sq. cm. from 200 to 400

Resistance against tear kgm./sq. cm. 500

Melting point, Centigrade between 210 and 215

Heat resistance Vicat centigrade between 160 and 180

Heat conductivity 10^8 cal./cm. sec. Centigrade from 50 to 60

Imbibition with water in weight, per cent. 12

It is resistant against boiling and steam sterilization. It can be produced in any desired shape. Thin threads of 0.15 mm. in diameter are available, as well as ribbons for the covering of bone defects in the skull or orthopedic prostheses. It can be welded, drilled sawed, and polished. It is however, not hard enough to replace steel in bone nails. It is not resorbed in the body but, in contradistinction to other materials, it does not cause any foreign body reaction in the tissues. It is much more solid and resistant against bending and traction than silk or catgut.

Because of these properties supramid is an ideal material for many purposes in surgery. In addition to its use for skin and muscle sutures and ligatures, it has been successfully used in suturing and replacing tendons, suturing spiral fractures of the tibia and humerus, transplanting bone, covering traumatic defects of the dura, and in plastic operations for saddle nose.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Obstructions of the Alimentary Tract in Infancy WILLIAM A. EVANS, JR. *Radiology* 1948 51 23.

With the increasing success in the treatment of the infectious diseases of infancy and childhood by the use of the various antibiotics and chemotherapeutic agents as well as the adequate meeting of the nutritional requirements in infancy the importance of congenital malformations assumes increasing stature. The advancing knowledge of surgical techniques and more accurate methods of diagnosis make a number of previously hopeless congenital lesions of the alimentary tract amenable to some degree of correction.

The author reviews the more common obstructing or potentially obstructing lesions of the alimentary tract in 400 infants seen at the Children's Hospital of Michigan, Detroit, in the past 7 years. While 50 per cent of the lesions seen were diagnosed as hypertrophic pyloric stenosis, only 19 per cent of these were subjected to radiological examination. The age of greatest incidence in this group of infants was 6 weeks.

Twenty per cent of the lesions seen were due to intussusception and only 30 per cent of these were subjected to radiological examination. The age of greatest incidence in this group was 5 months. Atresia meconium ileus constricting bands, and volvulus comprised only 23 per cent of the lesions but this was the group that received most of the roentgen examination.

A brief clinical and radiological review of the pertinent points in the diagnosis of each of the lesions is given. Mention is made of functional obstructions of the alimentary tract resulting from intracranial birth injuries, as well as congenital absence of nerve cells in the lower ileum or colon. Diaphragmatic hernia is mentioned as an occasional cause of obstruction in the very young.

ROY GREENBERG, M.D.

The Roentgen Appearance of the Chest in Diseases Affecting the Peripheral Vascular System of the Lungs. Conditions Associated with Increased Vascular Permeability ROBERT P. BARDEEN AND DAVID A. COOPER. *Radiology* 1948, 51 44.

This article considers the roentgen appearance of the chest in certain clinical states associated with increased permeability of the pulmonary vascular system. A table listing many of the disease conditions affecting these blood vessels in this way is included. By means of a chest roentgenogram the changes produced by the altered permeability of the pulmonary vessels can be visualized and this reflects the condition of the peripheral vascular system in general. Reproductions of roentgenograms illustrating these changes accompany a discussion of the following

clinical conditions in which alterations in the permeability of the pulmonary vascular bed occur: trauma to the chest, epidemic influenza, disseminated lupus erythematosus, acute rheumatic fever, exfoliative dermatitis, acute glomerulonephritis, periarthritis nodosa, and Loeffler's syndrome.

The authors point out that these diseases all present a rather uniform pathological, clinical, and radiological pattern that results from the changes produced in the peripheral vascular system by hypersensitive states. Indeed it is the hypersensitive reaction in the individual patient, which may be caused by a multiplicity of disease agents that is the common denominator. The pulmonary vessels participate in this reaction and produce a fairly characteristic roentgen appearance of a bilateral symmetrical patchy to uniform haziness usually in the upper portions of the lung fields either peripherally or in a peripheral location. These infiltrations are transient and change rapidly making serial examinations necessary in order to ascertain that they are characteristic of peripheral pulmonary vascular disease. The radiologist, by being cognizant of this type of reaction in the vascular system of the lungs, can more effectively aid the clinician in arriving at a diagnosis.

D. B. NADEL, M.D.

Some Considerations of the Roentgen Diagnosis of Silicosis and the Conditions that may Simulate It. EUGENE P. PENDERGRASS AND ADELETTA G. ROBERT. *Radiology* 1948 50 725.

The authors emphasize the fact that a fluoroscopic and roentgenographic examination of the chest constitutes the best method for demonstrating in the living individual the pathologic changes produced by pneumoconiosis or silicosis. It is necessary however to correlate the roentgen findings with all other available data before a proper diagnosis can be made. An ideal although somewhat too ambitious, arrangement would be to have a group of consultants consisting of a general physician, a rhinologist, a bronchologist, a clinical pathologist, a specialist in tuberculosis, a physiologist interested in the heart and lungs, an engineer (expert in industrial hygiene) and a general roentgenologist.

"Pneumoconiosis" is a broad generic term which includes all forms of pulmonary reaction due to dust lodging within the lungs. A subdivision into the specific (silicosis and asbestosis) and nonspecific or benign pneumoconiosis has certain practical advantages. The former may be productive of disability whereas the latter is of clinical significance only because it may lead to error in diagnosis.

The common features of silicosis and asbestosis are that they result from inhalation of the dust, are capable of producing a progressive pulmonary fibrosis and lead to characteristic though radically different roentgen images.

The silicosis is due to the specific action of the chemically free silicon dioxide in finely divided form on the lung tissue. The inhaled dust first exerts its toxic influence within the bodies of the alveolar phagocytes. Degenerative changes, easily confused with those in the "epithelioid" cells of tuberculosis quickly become evident. Lipoid deposition and giant-cell formation constitute part of the picture. The migrating phagocytes eventually concentrate the silica in and about the pulmonary lymphatics stimulating consecutive tissue proliferation and resulting in the formation of the silicotic nodules situated in the immediate vicinity of the lymphatic vessels. The alveolar phagocytes will collect upon the walls of the air spaces proper and lead to the formation of parenchymal silicotic nodules.

Some inert dusts, as for example aluminum when mixed with free silica may cause a retardation in the development of the silicotic process.

On the other hand silicosis increases the susceptibility to tuberculosis. Two facts must be stressed (1) that it is the presence of associated infection which accounts for most of the disability arising from silicosis and (2) that infection when it occurs may manifest itself in either of two ways namely by the development of tuberculo-silicosis or of silicosis with tuberculosis the latter being the less frequent.

The criteria for diagnosis of silicosis include a positive history of sufficient exposure to free silica dust, the roentgen demonstration of characteristic shadows and various physical and laboratory findings which exclude other conditions.

The roentgen manifestations of simple silicosis and of silicosis complicated by the presence of coexisting infection are detailed. The demonstration of a generalized nodulation uniformly distributed throughout the pulmonary parenchyma is of fundamental importance in simple silicosis. A subdivision into the three stages in the development of which Gardner and Sampson had a prominent role may have some practical value but according to the authors it is the nature of the lesion that should invariably be emphasized rather than the stage of development.

The tuberculo-silicosis is a distinct entity resulting from prolonged interaction of the two disease processes but differs radically in its behavior from either occurring alone. Therefore the roentgen manifestations may be quite variable and necessitate repeated careful studies.

Silicosis with tuberculosis occur in one of two forms either (1) the result of infection superimposed upon a progressive and still active silicosis or (2) as the result of infection superimposed upon an old and already stabilized silicotic process. In both groups the infection component is first identified on the roentgenograms by simple or multiple areas of infiltration or mottling superimposed upon a background of discrete nodulation. The subsequent behavior, however may lead to roentgen images rather difficult of interpretation.

The criteria for the diagnosis of a metastasis are not reviewed in the present article.

Of the nonspecific pneumoconioses, the authors briefly discuss baritosis, siderosis, the pseudonodulation due to inhalation of tin oxide, the talc pneumoconiosis and the pneumoconiosis due to vanadium pentoxide.

Other confusing causes of nodular densities within the lungs are also discussed. These include tuberculosis, histoplasmosis, mycotic infections, hemangiosarcoma, polycythemia vera, metastatic carcinoma, Boeck's sarcoid and the chronic pulmonary granulomatosis in beryllium workers.

The article is abundantly illustrated with roentgenograms and a bibliography of numerous articles is appended. T. LAROCHE, M.D.

The Roentgen Diagnosis of Rickets Associated with Other Skeletal Diseases of Infants and Children. RALPH S. BROWNE AND R. LEE M. HARRY. *Radiology* 1935, 31:1.

The simultaneous occurrence of rickets with scurvy, congenital syphilis, lead poisoning, erythroblastic anemia, and osteogenesis imperfecta is discussed.

When rickets and scurvy occur simultaneously the problem of recognition is difficult. However the authors believe that the diagnosis can be made with a high percentage of accuracy in certain cases. In most of the combined cases the signs of scurvy obscure those of rickets unless the latter is severe.

The signs of identification of the combined diseases are:

1. Rarefaction of the cortex is of the rachitic moth-eaten type rather than the scorbutic ground-glass type.

2. In the enchondral metaphyseal area the signs of rickets predominate and may prevent the characteristic signs of scurvy.

3. In combined cases the osteoid zone of rickets can be diagnosed by a marked increase in the clear space between the epiphyseal center and the end of the diaphysis.

4. In the combined cases the ring sign about the epiphyseal center remains intact, which is indicative of scurvy.

5. Spreading of the diaphyseal ends cannot be considered indicative of either one or the other of the diseases. The distinction between the lateral spur of scurvy and the cupping of the diaphyseal ends of rickets can be made only by vertical projections through the zone of temporary calcification.

6. Periosteal triangular shadows of slight width compared to those usually seen in scurvy are indicative of scorbutic hemorrhage merged with rachitic periosteal elevation.

When rickets and syphilis coexist the only signs present are those of rickets. The periosteal involvement is so similar in the two conditions that differentiation is impossible.

In rickets with lead poisoning the characteristic lead line at the diaphyseal ends of the long bones fails to develop.

The authors quote the case of Caffey (*Am. J. Roentg.* 1937 37:203) in which rickets was super-

imposed on erythroblastic anemia but state only that the diagnosis of rickets could be made roentgenologically

The case of osteogenesis imperfecta in which rickets and scurvy developed was reported previously by Bromer (*Am. J. Roentg.* 1946 55 30) This case showed the signs of osteogenesis imperfecta and the usual signs of rickets i.e. decalcification flaring of the diaphyseal region of one radius, and an osteoid zone distal to the frayed out zone of preparatory calcification Six months later the child had unmistakable signs of scurvy JOHN O. LAFERTY M.D.

The Skeletal Lesions in Leukemia FREDERIC \ SILVERMAN *Am. J. Roentg.* 1948 59 819.

The author reports the clinical and roentgenographic observations in 103 leukemic infants and children who were admitted to the Babies Hospital in New York during the period from 1924 to 1947 The ages at the onset of the symptoms varied from 22 days to 12 years and 7 months. More than 70 per cent of the patients died within 7 months after the clinical onset of their disease. Abnormal white blood cells were found in the peripheral circulation in 102 of the 103 cases. Forty patients had persistently high counts that is above 12,000 white blood cells per cubic millimeter and 27 had persistently low counts below 12,000. The presence of an increased erythrocyte sedimentation rate was a related finding in almost all of the cases. Fifty two of the 103 leukemic children showed bone changes in their roentgenograms. Four types of lesions were found: transverse bands of diminished density, osteolysis, osteosclerosis and subperiosteal new formation of bone.

Frequently more than one type of lesion was present in a single patient. Forty two patients complained of pain. 25 had skeletal lesions demonstrable in roentgenograms, and 17 presented no lesions. No significant correlation was observed between the sites of the pain and the sites of the lesions. Seventeen patients complained of pain but showed no lesions. Of the 52 patients with lesions 25 had pain and 27 had no pain. Thirty-four of the 103 patients had no lesions and no skeletal pain. Transverse bands of diminished density occurred at the ends of the shafts of long bones in 14 patients. Osteolytic lesions occurred in 39 patients, osteosclerosis occurred in 9 patients and subperiosteal new bone formation occurred in 17 patients.

Associated roentgen findings outside of the skeletal system which were often helpful in the diagnosis were enlargement of the lymph nodes, mediastinal tumors and enlargement of the adenoids.

The diagnosis of leukemia in infants and children is often made difficult by factors which do not operate significantly in adults. Chief among these are the tendency of nonleukemic children to produce immature white blood cells in response to severe infections and the frequent absence of leukocytosis in children with leukemia. The demonstration of leukemic changes in the bones by roentgen examination

provides valuable information for the detection of leukemia during early life.

FRANK L. HUSKEY M.D.

Studies of the Circulation by Roentgen Cinematography NILS WESTERMARK. *Radiology* 1948, 50 791

The author reviews the experimental work that had been carried out formerly by various methods for the study of the velocity and circulation time of the blood and their relationship to the cardiac contraction. He also discusses the earlier physiological attempts at recording the cardiac movements. In particular the role of the movements of the atrioventricular junction for driving out the blood from the ventricle is stressed.

In a recent publication the author described how roentgen cinematographic and simultaneous electrocardiographic examinations were carried out on the hearts of sheep with metallic indicators implanted in the myocardium in different parts of the left ventricle. By this method some new observations were made on the expulsion of the blood from the ventricle.

Our knowledge of the dynamics of the heart is based mainly upon pressure curves taken simultaneously from different parts of the organ and from the vessels. Lewis has established diagrams representing the curves of pressure in the carotid artery, aorta, left ventricle and right auricle of the human being and demonstrated the supposed or ascertained time relations of these curves, the jugular pulse curve, the electrocardiogram and apical heart sounds to each other. The author reproduces Lewis diagrams and discusses the various factors in lengthy detail.

He then proceeds to describe the technique of his own experimental study of cardiac contraction and its relationship to the blood circulation by means of indirect roentgen cinematography of the contrast filled circulatory system. The experiments were carried out in rabbits by injecting 20 gm. of thorast contrast corresponding to 1 or 1.4 per cent of the body weight of the animal into the jugular vein. The circulation was recorded by cinematography of the fluorescent image produced by roentgen exposure. The timing of the various phases of the circulatory cycle was determined by means of electrocardiograms which were made simultaneously, a photo tube being used for the synchronization. The thorast was found to mix well with the blood and gave a homogeneous shadow. Altogether 50 experiments were made.

It was found that the rapid inflow of the blood into the ventricles occurs during the presystole and not at the beginning of the diastole as was formerly assumed. The expulsion of contrast blood from the ventricles would also seem to occur later than demonstrated by pressure determinations.

According to the experiments the expulsion through the arterial ostia occurs at the beginning of T and not immediately after S as shown by pressure determinations. The closing of the atrioventric

ular and semilunar valves takes place as observed formerly.

The author gives the following interpretation of these observations.

It seems probable that the systolic contraction of the ventricle begins with a contraction of the inter-ventricular system, in which the septum is shortened and the central part of the atrioventricular function is drawn toward the cardiac apex. When this contracts, the wall swells and the inner contour of the apex moves, together with the septum toward the base, the retrograde movement of the atrioventricular function taking place simultaneously. Then the contraction will continue along the external ventricular walls up toward the arterial ostia. This continuous systolic contraction starts with the commencement of the QRS-complex and finishes at the end of T when the contrast blood has been almost completely expelled from the ventricles and the semilunar valves are closed. Systole once complete the ventricles will not relax immediately. This might explain the fact that no filling of the ventricles is distinguishable until P when rapid flow of contrast blood to the ventricle sets in. T. LEVOTZ, M.D.

Röntgen Treatment for Extensive Epithelioma of the Larynx; Results in 139 Cases. ARTHUR U. DESJARDINS, FREDERICK A. FOL, and LUTHER M. VAUGHAN. *Am. J. Roentg.* 1948, 60, 9.

The authors review and analyze a series of 139 cases in which epithelioma of the larynx had been treated with fractional doses of roentgen rays from 1936 through 1945. All the patients had extensive epithelioma and in most of them the neoplasms were so extensive that surgical treatment was not considered advisable.

In 56 of all the patients included in this series of 139, tracheotomy was not performed at any time. Tracheotomy was performed before roentgen treatment in 76 cases during the course of roentgen treatment in only 1 case and soon after the course of treatment in 6 cases.

All patients were treated with rays generated at 200 peak kilovolts, filtered through a Thoracuss filter consisting of 0.44 mm. of tin, 0.35 mm. of copper and 1.0 mm. of aluminum at a focal-skin distance of 50 cm. The half value layer was equivalent to 1.75 mm. of copper. In most cases the treatment was given through two lateral fields (one on each side) each of which measured from 8 by 12 cm. to 12 by 18 cm. but in a small number of cases the treatment was given through three fields (two on one side and one on the other). When two fields on one side were employed, they were on the side on which the bulk of the malignant process was situated.

Of the 139 patients in the entire series, 77 were treated between 1935 and 1945 inclusive and of 3 of these the authors were unable to obtain recent information. This left 68 patients who were treated during this period and who were living more than 3 years since their treatment at the Mayo Clinic. As percentages of "cured cases" go, this proportion is

not as high as might be expected but, considering the initially unfavorable character of these cases and the extensive malignant neoplasms from which the patients suffered even this percentage seems worthy of consideration. There is no doubt that if these patients had not been treated in the manner described by the authors all of them must inevitably have died in short order. Moreover the pronounced relief of symptoms and improvement in the general condition which in the patients who died, had occurred after treatment cannot be estimated.

Röntgen Therapy of Malignant Tumors of the Testis. EVONER T. LINDOR. *Am. J. Roentg.* 1948, 60, 39.

Seminomas and malignant teratomas together constitute about 95 per cent of all malignant tumors of the testis. Seminomas are encountered about six times more frequently than malignant teratomas. Both of these tumors occur during the years of greatest sexual potency, but the maximal incidence of teratomas occurs earlier in life than does the maximal incidence of seminomas.

The author states that the adoption of Broders classification would go a long way toward correcting the confusing and contradictory views about testicular tumors.

A distinction by the pathologist of seminoma from malignant teratoma gives the basic indications on which roentgen therapy may be planned. Orchiectomy is advised both as a diagnostic and therapeutic procedure even in the presence of known metastatic lesions in all but very exceptional cases. After a brief period of postoperative convalescence it is the practice at the Mayo Clinic to administer a course of postoperative radiotherapy. Recently malignant teratomas have been exempted. Radium was used in the early days, but because roentgen therapy is, as a rule, more practical, more efficient, and more expedient than radium therapy radium is now seldom used.

It was the author's opinion at the time the report was written, that irradiation of seminomas of the testis and their secondary deposits could best be carried out with roentgen rays of moderate voltage (130 to 140 kv). Prophylactic postoperative treatment, if it is to be truly protective against metastasis, should be applied to all lymphatic pathways through which metastasis may take place. This, obviously makes extensive treatment necessary.

Some tumors may be a mixture of a seminoma and a teratoma. In this case, the initial response of the tumor may be satisfactory because the seminoma is destroyed however after the initial response has taken place the residual tumor may not respond and the tumor may grow in spite of treatment. For the treatment of seminomas, roentgen therapy has assumed a position of prime importance and has altered the prognosis from one of hopelessness to one of subdued optimism.

Since the radiosensitivity and, therefore, the prognosis of seminomas are completely different

from the radiosensitivity and prognosis of malignant teratomas accurate pathologic diagnosis as a basis for roentgen treatment is justified. The author describes a method of treatment which is said to be as effective as any reported and safer than many it is based on extensive experience

MISCELLANEOUS

Neutron Therapy and Specific Ionization *Jane-
way Memorial Lecture, 1947 ROBERT S. STONE.
Am J Roentg., 1948, 59 771*

The author reviews the results of intensive treatment of human cancer between 1938 and 1943 with neutrons. Neutrons are particles of matter of the same weight as the nuclei of hydrogen atoms. They have no electrical charge. They are obtained by knocking them out of atomic nuclei by bombardment with high energy photons or atomic particles. The physical measurement of neutron radiation in air in units that can be translated to tissue doses comparable to tissue roentgens has been difficult. The N unit of exposure is physically equivalent to about 2.5 roentgens as judged by the amount of energy absorbed from a beam by tissue. In other words 1 N equals 2.5 rep (roentgen equivalent physical). The biological work on the Plutonium Project, and the work on human beings here reported show that the relative biological effectiveness of neutrons compared to roentgen rays is greater in the late results than in the early ones.

The method used at the University of California to obtain a beam of fast neutrons was by means of the cyclotron devised by E. O. Lawrence. From September 26 1938 until June 20, 1939 a total of 24 patients were treated on the 37 inch cyclotron with 8 mev deuterons to produce the fast neutrons. Beginning in November 1939 and up to February 1943 the cyclotron with 60 inch pole faces which gave deuterons with 16 mev of energy was used. The total number of patients treated was 226. Thirty-one patients did

not complete their courses of treatment. A few of the patients had only one treatment. One patient was treated on both cyclotrons and is included in both totals. On January 1 1948 17 of the patients were alive and all but one who lacked only 1 month had lived more than 5 years from the day of his first treatment. All of the patients with one exception who were treated with fast neutrons were considered incurable. All kinds of malignant conditions were treated. Many of the patients had had previous treatment with other methods. Sixteen patients who received complete courses of treatment with fractionated doses of fast neutrons have been observed for more than 5 years. Thirteen of them had severe epidermolytic reactions in all treated areas. 1 had epidermolysis in one of the 3 fields. 1 had an erythematous reaction and 1 had only desquamation. Most of them had severe early reactions. Eighteen patients were kept alive. They all had severe late reactions. 12 of them had such severe changes that they were partially incapacitated. The late tissue reactions consisted of marked skin atrophy telangiectasis loss of subcutaneous fat, contractions of the scarred area, and fibrosis of the muscles. In lesions of the mouth, pharynx, and larynx there was persistent ulceration at the site of tumor regression. Some of the patients with lesions that were treated through the mandible developed radiation osteitis. When treatments were given through the pelvis the effects on the intestine were quite severe.

From the study of the patients treated with neutrons it is clear that cancer cells can be killed and patients cured of their cancer but the difference between the dose required to kill cancer and that to damage normal tissue acutely is very small. Eighteen patients were kept alive but none of them were free from distressing late effects. Anyone contemplating the use of new radiations, such as multimillion volt protons, beta rays, and roentgen rays on patients should study their late biological reactions as well as their acute early ones. FRANK L. HUSKEY M.D.

Yet if the foregoing possibilities are borne constantly in mind the results achieved often justify the risks involved. The procedure itself is basically simple and the apparatus can be constructed and assembled in any hospital. Facilities for preparing sterile perfusion fluid in large amounts must be available as well as an adequate clinical laboratory for analysis of the blood counts, chemical examination of the blood and the other indicated studies. Beyond this is needed an interested clinician informed as to the basic physiology of the peritoneum as a dialyzing membrane and as to the water and electrolyte requirements of the patient, and with mind and eye alert for the development of complications.

It is the opinion of the authors that when acute suppression of renal function with increasing renal insufficiency develops several days of routine intravenous therapy and supportive measures should first be employed in an attempt to promote the formation of urine. If at the end of this time conservative measures have failed and it appears that fatal termination of the case may result, the procedure of peritoneal lavage should be initiated as a lifesaving measure. A discussion of procedures and the data pertaining to 6 cases is included.

The Rapid Injection of a Solution of Amino Acids.

RICHARD D. ECKHARDT and CHARLES S. DAVIDSON
England J. M. 1948, 229-164.

A 10 per cent solution of amino acids prepared by the complete acid hydrolysis of casein devoid of peptides, largely freed of glutamic and aspartic acids and supplemented with DL tryptophane and glycine was administered 34 times to 62 subjects at the Thorndike Memorial Laboratory Boston City Hospital Boston.

Over 70 per cent of all infusions were administered at rates usually unattainable with the previously available protein hydrolysates (50 gm of amino acids in 70-kgm subjects in less than an hour). All injections supplied at least 0.5 gm of protein per kilogram of body weight and many of them were larger.

The clinical tolerance of the solution of amino acids was evaluated in normal subjects as well as in patients with a variety of illnesses requiring parental protein therapy. However, there was no apparent difference in the clinical tolerance of the amino acid solution whether it was given with glucose saline solution lactate or vitamins or when it was given repeatedly.

The incidence of pyrogenic reactions was 0.3 per cent, nausea, 0.4 per cent, vomiting, 2.6 per cent, venous thrombosis, 2.3 per cent and transient anorexia 0.1 per cent.

Because of the rapid rates of infusion attainable with but few untoward reactions, it was concluded that the solution of amino acids employed in this study was better tolerated in man than the protein hydrolysates previously used.

ROBERT MAYO TENNEY M.D.

Calcifying Epitheliomas of the Skin (Type Malherbe)

KAI SERRA, *Ann. chir. gyn. fenn.*, 1948 37 Supp. 3

The author examined 29 cases of a new type of tumor. These calcifying epitheliomas were located in the subcutis and seemed to lack even a slight epithelial connection with the overlying dermis. The tumor itself was composed of numerous epithelial cell masses or bands each of these being separately surrounded by a single layered mantle composed of cuboidal or cylindrical epithelial cells. The medullary portion was formed of squamous-celled elements, which possessed a particular tendency to retrogressive alterations. The tumor was surrounded by a connective tissue capsule which often showed a well developed network of capillaries. The tendency of the epithelial portion to form tissue of a lower vitality was no doubt the essential factor in influencing the microscopical picture of the calcifying epitheliomas. From the surrounding capsule like formation, newly formed invading connective tissue grew and replaced the changing epithelium. This connective tissue had either undergone hyaline degeneration and later become calcified or had actually begun to ossify.

The author expresses the opinion that the calcifying epitheliomas might be derived from hair follicles. The microscopical examination revealed in 3 cases signs which justify the statement that the tumor may be only 'locally' malignant. In none of the cases had the infiltrative destructive growth progressed far enough to destroy the surroundings to any extent.

JAMES WEAVER, M.D.

Hemangiomas of Striated Muscle. C. FRED GORE *INQUIR. Am. J. Surg.* 1948 76 58.

The author reports 3 cases of hemangioma of striated muscle. The first was that of a Chinese 22 years old who had a 1 year history of swelling of the lower inner aspect of the right thigh. A cavernous hemangioma of the sartorius muscle was found and excised. Only one other case has been described in which the tumor was confined entirely to that structure. Case 2 was that of a 19 year old white female complaining of pain in the left calf and inability to dorsiflex the left foot of 3 years duration. A cavernous hemangioma of the calf muscles was found and removed. Case 3 was that of a 15 year old school girl who complained of a swelling of the inner aspect of the left elbow noted 5 years previously. At operation the tumor was found to consist of dilated veins in the substance of the flexor sublimis digitorum muscle. The upper 2 inches of the muscle was removed and the lesion proved to be a cavernous hemangioma.

Almost half of the patients whose cases were recorded in the literature displayed symptoms before the age of 11 years. It is a disease that usually occurs in the first three decades. The incidence of hemangiomas is approximately equal in males and females. These tumors are predominantly congenital in origin. The lesion presumably arises in the vascular plexus of the muscle or in the peri-

CARCINOMA CELLS IN SPUTUM AND BRONCHIAL SECRETIONS

A Study of 150 Consecutive Cases in Which Results Were Positive

LEWIS B. WOOLNER, M.D., and JOHN R. McDONALD, M.D., Rochester, Minnesota

THE occurrence of grossly visible fragments of neoplastic tissue in the sputum of patients with cancer of the lung has been observed for many years. While such an occurrence is rare and usually indicates far advanced disease, an occasional diagnosis of bronchogenic carcinoma has been made by embedding and sectioning the tumor tissue so obtained. Betschart in 1895 reported a case of bronchogenic carcinoma in which the diagnosis was made by section of tumor fragments present in the sputum and cited 3 previous reports of cases in the literature. Similar diagnoses based on gross particles or sputum section were subsequently reported by a number of investigators including Sauerbruch in 1908, Bezangon and de Jong in 1913, Fishberg in 1926, Weller in 1929, Sweany in 1934, Hill in 1934, Edwards in 1934, and Holinger and associates in 1945. The technique employed by these workers involved ordinary histologic exami-

nation of tumor fragments or sputum embedded and sectioned in the usual manner. In general the results were not considered of great value in the diagnosis of bronchogenic carcinoma.

The first report of the cytologic examination of sputum in a case of bronchogenic carcinoma was made by Hampeln (10) in 1887. He found large atypical epithelial cells in the sputum which he believed were diagnostic of carcinoma. His technique was simply the microscopic examination of unstained smears of fresh sputum. In a second paper in 1918 Hampeln (11) reported 25 cases of pulmonary cancer in 13 of which carcinoma cells were found in the sputum. Hampeln stressed the diagnostic importance of isolated neoplastic cells in contrast to other workers who held that a histologic section of an actual fragment of tissue was necessary for the diagnosis of carcinoma.

In spite of Hampeln's work little attention was paid to the possibilities of cytologic study of sputum until the introduction of a new technique by Dudgeon and Wrigley of London in 1935. This method consisted essentially in

CARCINOMA CELLS IN SPUTUM AND BRONCHIAL SECRETIONS

A Study of 150 Consecutive Cases in Which Results Were Positive

LEWIS B. WOOLNER, M.D., and JOHN R. McDONALD, M.D., Rochester, Minnesota

THE occurrence of grossly visible fragments of neoplastic tissue in the sputum of patients with cancer of the lung has been observed for many years. While such an occurrence is rare and usually indicates far advanced disease, an occasional diagnosis of bronchogenic carcinoma has been made by embedding and sectioning the tumor tissue so obtained. Betschart in 1895 reported a case of bronchogenic carcinoma in which the diagnosis was made by section of tumor fragments present in the sputum and cited 3 previous reports of cases in the literature. Similar diagnoses based on gross particles or sputum section were subsequently reported by a number of investigators including Sauerbruch in 1908, Bezançon and de Jong in 1913, Fishberg in 1926, Weller in 1929, Sweany in 1934, Hill in 1934, Edwards in 1934, and Hollinger and associates in 1945. The technique employed by these workers involved ordinary histologic exami-

nation of tumor fragments or sputum embedded and sectioned in the usual manner. In general the results were not considered of great value in the diagnosis of bronchogenic carcinoma.

The first report of the *cytologic* examination of sputum in a case of bronchogenic carcinoma was made by Hampeln (10) in 1887. He found large atypical epithelial cells in the sputum which he believed were diagnostic of carcinoma. His technique was simply the microscopic examination of unstained smears of fresh sputum. In a second paper in 1918 Hampeln (11) reported 25 cases of pulmonary cancer in 13 of which carcinoma cells were found in the sputum. Hampeln stressed the diagnostic importance of isolated neoplastic cells in contrast to other workers who held that a histologic section of an actual fragment of tissue was necessary for the diagnosis of carcinoma.

In spite of Hampeln's work, little attention was paid to the possibilities of cytologic study of sputum until the introduction of a new technique by Dudgeon and Wrigley of London in 1935. This method consisted essentially in

the making of films of fresh sputum fixing while wet in Schaudinn's solution and staining with hematoxylin and eosin. The basis for this new technique was the 'wet film' method of examination of fresh tissues described by Dudgeon and Patrick in 1927 and Dudgeon and Barrett in 1934. According to this procedure fresh tissues were scraped with a scalpel and the resulting suspension of cells transferred to a glass slide. Smears so obtained were fixed while wet in Schaudinn's fluid and stained with hematoxylin and eosin. By this means it was found possible to recognize malignant cells as such when separated from their usual surroundings. After eight years of experience with the wet film method in the study of fresh tissues Dudgeon and Wrigley employed the same technique to the study of sputum with equally successful results. In 68 per cent of 58 cases of proved carcinoma of the lung or respiratory tract malignant cells were demonstrated in the sputum. In the majority of cases these authors were able to predict the histologic type of growth present in the bronchus by a study of the sputum. One false positive result occurred in this series, the atypical cells arising in an inflammatory lesion.

Using a similar technique Barrett reported positive results in 68 of 110 proved cases of bronchogenic carcinoma while Gower obtained positive results in 64 per cent of 93 cases in which the sputum was investigated.

A very thorough study of the subject was reported by Wandall of Copenhagen in 1944. The material comprised 250 patients, 100 of whom had primary bronchogenic carcinoma. Of this group of 100 cases carcinoma cells were found in the sputum in 84. The technique used was that of Dudgeon and Wrigley in which Schaudinn's fixative and hematoxylin and eosin stains were used. Eighty-two of the 100 patients with bronchogenic carcinoma underwent bronchoscopy. Biopsy gave positive results in 55 per cent. Examination of the sputum in this group gave the higher figure of 82 per cent positive results. Combining both these methods Wandall found that a positive diagnosis of carcinoma could be made in 94 per cent of cases. Of 193 instances of sputum examination in which the clinical rec-

ord was entirely unknown a false positive result was given in 6, a percentile error of 3.1. Wandall concluded that a search for neoplastic cells in sputum should be introduced as an important link in the examination of patients believed to be suffering from primary bronchogenic carcinoma.

A study of bronchoscopically removed sections was carried out by Herbut and Clerf (12) in 1946. These authors expressed the belief that the examination of bronchial secretions is superior to the examination of sputum by reason of the increased dilution of the latter. Bronchoscopic removal of secretions from the region of the suspected tumor serves further to localize the source of the malignant cells. Positive results were obtained in 82.4 per cent of 57 proved cases of bronchogenic carcinoma. The results of bronchoscopic biopsy in this series were positive in 42 per cent. A positive diagnosis in 25 of their final 27 cases (92.5 per cent) led these authors (13) to conclude that in most cases of carcinoma of the lung the diagnosis can be made by means of cytologic study of bronchoscopically removed sections.

Papanicolaou (16, 18, 19) for many years has stressed the value of the smear test as a basis for the diagnosis of malignant neoplasms having a free surface. While primarily concerned with cytologic study of vaginal secretions in the diagnosis of uterine cancer, he has reported results of sputum examination in 25 cases of carcinoma of the lung (17). In 22 of these cases (88 per cent) the sputum smears were positive for malignant cells. No false positive reports were given in this series.

PLAN OF THE PRESENT STUDY

The problems involved in this study were threefold: (1) to become familiar with the appearance of carcinoma cells in sputum and bronchial secretions as well as normal cells in all their variations, (2) to work out technical details of collection, smearing, fixation and staining of material, and (3) to evaluate the method as a routine procedure to be used in the diagnosis of primary bronchogenic carcinoma. A preliminary period of study on sputum or secretions removed bronchoscopically from patients known to have carcinoma and from patients known not to have carcinoma

Fig. 1. Normal cells in sputum and bronchial secretions stained with hematoxylin and eosin. a. Squamous epithelial cells (X600). b. Ciliated columnar epithelial cell (X600). c. Pigmented macrophages (X640).

was carried out. In addition smears were made from bronchial secretions of lungs removed surgically for bronchogenic carcinoma. In other instances the surface of the tumor itself was gently scraped and the resulting emulsion of cells smeared, fixed and examined. By this means familiarity with the appearance of carcinoma cells occurring apart from their normal environment was gradually acquired. Various methods of fixation and staining were tried to determine the best technique for routine laboratory work.

After this preliminary study specimens of sputum or bronchial secretions were studied as unknowns and positive or negative results were reported. In doubtful cases a second or even a third specimen was examined. In all sputum or bronchial secretions were examined for carcinoma cell from a total of 1,600 patients. In 150 of these cases results were reported as positive and in 1,450 they were considered negative. No follow-up studies were done on the group of patient for whom the results were negative but the vast majority were considered to have nonneoplastic lesion.

After positive results in 150 consecutive cases were reported the results were tabulated and analyzed.

TECHNIQUE

The methods of collection of specimens, preparations of smears, fixation and staining have been outlined in a previous report by the authors (24). The staining method used routinely is Harris hematoxylin with dilute eosin as a counterstain. It has proved entirely satisfactory for nuclear detail, the factor on which the diagnosis is primarily based, and has the advantage of familiarity to pathologists.

Examination of smears. Five smears from each specimen are fixed and stained according to the aforementioned technique. The films are then carefully scanned under low power, the high dry objective being used to study cell detail. It may be useful to mark suspicious cells or clumps with ink and later to return for careful consideration of these areas. The number of carcinoma cells per slide in a case of carcinoma varies considerably. In rare cases almost every low power field will show malignant cells. In many cases each slide will contain a few scattered clumps and isolated single cancer cells. Occasionally only one or two of the five slides will give positive result. For this reason it is important that all slides in a given case be examined methodically, a mechanical stage being used if necessary. The

the making of films of fresh sputum fixing while wet, in Schaudinn's solution and staining with hematoxylin and eosin. The basis for this new technique was the wet film method of examination of fresh tissues described by Dudgeon and Patrick in 1927 and Dudgeon and Barrett in 1934. According to this procedure fresh tissues were scraped with a scalpel and the resulting suspension of cells transferred to a glass slide. Smears so obtained were fixed while wet, in Schaudinn's fluid and stained with hematoxylin and eosin. By this means it was found possible to recognize malignant cells as such when separated from their usual surroundings. After eight years of experience with the wet film method in the study of fresh tissues, Dudgeon and Wrigley employed the same technique to the study of sputum with equally successful results. In 68 per cent of 58 cases of proved carcinoma of the lung or respiratory tract, malignant cells were demonstrated in the sputum. In the majority of cases these authors were able to predict the histologic type of growth present in the bronchus by a study of the sputum. One false positive result occurred in this series, the atypical cells arising in an inflammatory lesion.

Using a similar technique Barrett reported positive results in 68 of 110 proved cases of bronchogenic carcinoma while Gowar obtained positive results in 64 per cent of 93 cases in which the sputum was investigated.

A very thorough study of the subject was reported by Wandall of Copenhagen in 1944. The material comprised 250 patients, 100 of whom had primary bronchogenic carcinoma. Of this group of 100 cases carcinoma cells were found in the sputum in 84. The technique used was that of Dudgeon and Wrigley in which Schaudinn's fixative and hematoxylin and eosin stains were used. Eighty-two of the 100 patients with bronchogenic carcinoma underwent bronchoscopy. Biopsy gave positive results in 55 per cent. Examination of the sputum in this group gave the higher figure of 82 per cent positive results. Combining both these methods, Wandall found that a positive diagnosis of carcinoma could be made in 94 per cent of cases. Of 103 instances of sputum examination in which the clinical rec-

ord was entirely unknown a false positive result was given in 6, a percentile error of 3.1. Wandall concluded that a search for neoplastic cells in sputum should be introduced as an important link in the examination of patients believed to be suffering from primary bronchogenic carcinoma.

A study of bronchoscopically removed sections was carried out by Herbut and Clerf (12) in 1946. These authors expressed the belief that the examination of bronchial secretions is superior to the examination of sputum by reason of the increased dilution of the latter. Bronchoscopic removal of secretions from the region of the suspected tumor serves further to localize the source of the malignant cells. Positive results were obtained in 82.4 per cent of 57 proved cases of bronchogenic carcinoma. The results of bronchoscopic biopsy in this series were positive in 42 per cent. A positive diagnosis in 25 of their final 27 cases (92.5 per cent) led these authors (13) to conclude that in most cases of carcinoma of the lung the diagnosis can be made by means of cytologic study of bronchoscopically removed secretions.

Papanicolaou (16, 18, 19) for many years has stressed the value of the smear test as a basis for the diagnosis of malignant neoplasms having a free surface. While primarily concerned with cytologic study of vaginal secretions in the diagnosis of uterine cancer, he has reported results of sputum examination in 25 cases of carcinoma of the lung (17). pyema bronchitis bronchial asthma and congestive heart failure. Once familiarity is gained with the normal cells carcinoma cells because of their highly atypical appearance can be diagnosed with confidence and with a high degree of accuracy.

CARCINOMA CELLS IN SPUTUM AND BRONCHIAL SECRETIONS

General characteristics of carcinoma cells. Exfoliated cancer cells in sputum or bronchial

secretions possess certain distinctive features on which a diagnosis of malignancy can be safely based. In general it may be said that all the characteristic features of malignant cells seen in tissue sections with the exception of invasion can be applied to isolated cells singly and in clumps occurring in sputum and bronchial secretions. No single atypical feature is in itself diagnostic. The diagnosis is based on the complete cytologic picture in a given case in which the cells may present

CARCINOMA CELLS IN SPUTUM AND BRONCHIAL SECRETIONS

General characteristics of carcinoma cells. Exfoliated cancer cells in sputum or bronchial

secretions possess certain distinctive features on which a diagnosis of malignancy can be safely based. In general it may be said that all the characteristic features of malignant cells seen in tissue sections, with the exception of invasion, can be applied to isolated cells singly and in clumps occurring in sputum and bronchial secretions. No single atypical feature is in itself diagnostic. The diagnosis is based on the complete cytologic picture in a given case in which the cells may present

any or all of the following atypical characteristics

Size—Carcinoma cells are in general much larger than the normal cells in sputum or bronchial secretions. In some cases, cells of such enormous nuclear dimensions can be found (Fig. 2a) as to preclude any possibility of error in the diagnosis of malignancy. In other instances the carcinoma cells while still large more nearly approach the size of normal cells and more reliance must be placed on other atypical features. In the small cell oat cell type of bronchogenic carcinoma the cells fall well within the range of size of normal cells the nucleus being only two or three times the diameter of a lymphocyte (Fig. 2b).

Nuclear cytoplasmic ratio—More important than the size of the cell itself is the size of the nucleus and the relation of nucleus to cytoplasm. In the malignant cell the nucleus is very large in relation to the amount of cytoplasm. In some highly undifferentiated tumors the relatively large nucleus is surrounded by a narrow rim of cytoplasm. In others as in the small cell carcinomas the carcinoma cell frequently appears as a naked nucleus. An exception to this general finding is seen in the cells of a keratinizing squamous cell carcinoma. Many of these cells show voluminous acidophilic cytoplasm indicating keratinization of individual cells.

Variation in size and shape—Variation in size and shape of the nuclei is an extremely important consideration. This can best be appreciated when small clumps or clusters of carcinoma cells are present (Fig. 2c). Small clumps of malignant cells are a frequent finding in smears and although not essential for a diagnosis of malignancy aid greatly in the ease of interpretation. Clumps of benign cells present a regularity of size shape and staining of the nuclei not seen in neoplastic tissue. Variation in size and shape of the cells is probably least marked in small cell carcinomas, but even in this type sufficient variation is present to differentiate these cells from normal. In sputum or secretions from highly malignant tumors variation in cell size may be extreme and tumor giant cells may be seen.

Variation in staining—Carcinoma cells possess distinctive staining properties which are

as apparent in smears as in tissue sections. Nuclei of carcinoma cells generally are hyperchromatic and show a coarse chromatin network. In many cases carcinoma cells possess unusually large often multiple nucleoli of irregular shape and size (Fig. 2d). The nucleoli may appear basophilic or acidophilic and, when prominent, offer a definite aid in diagnosis. Details of nuclear structure are most important and for this reason a uniform and consistent staining technique must be developed. It should be noted that good nuclear detail may not be present in all atypical cells found in the smear. Careful search may be necessary to find well preserved cells with characteristic features on which a diagnosis of carcinoma may be safely based.

Mitotic figures.—In general cells undergoing mitosis are rarely found in smears of sputum or bronchial secretions and are of no importance in the diagnosis of carcinoma by this technique. Even in rapidly growing tumors as shown by tissue section mitotic figures are rarely found in the exfoliated cancer cells examined in the smear.

Special characteristics of carcinoma cells according to histologic type—Exfoliated cancer cells vary somewhat in appearance according to the histologic type of tumor present in the bronchus (Figs. 3, 4, frontispiece and 5). These tumors can be classified into four main groups: (1) small cell oat-cell carcinoma, (2) undifferentiated large cell carcinoma, (3) squamous cell carcinoma in which cell keratinization or pearly body formation is noted, and (4) adenocarcinoma characterized by the production of mucus or by gland formation. To these should be added so called alveolar cell carcinomas representing a small group of primary pulmonary neoplasms and presenting a characteristic gross and histologic pattern.

Carcinoma cells are found in the sputum in all these types and in certain instances are sufficiently distinctive to predict the histologic type of tumor in the bronchus. This is true especially of small cell carcinomas and keratinizing squamous cell carcinomas. In other cases especially in highly undifferentiated tumors, a diagnosis of carcinoma cells present is made without reference to type. Occasionally the problem arises as to whether a given

Fig. 3 Readily identified histologic types of exfoliated carcinoma cells in sputum (hematoxylin and eosin stain) a. Sputum smear from a bronchogenic carcinoma of small cell "oat-cell" type ($\times 640$) and b. corresponding tissue section ($\times 640$). Note similarity of cells. c. Carcinoma cells in sputum from an undifferentiated large cell bronchogenic carcinoma showing large nuclei and prominent nucleoli ($\times 640$) and d. corresponding tissue section ($\times 640$). e. Smear from bronchogenic carcinoma of squamous type showing large amount of cytoplasm and, f. tissue section of keratinizing squamous cell carcinoma ($\times 165$).

pulmonary tumor is primary or metastatic. The presence of small 'oat-cell' or squamous carcinoma cells may in such cases aid in establishing a diagnosis of primary bronchogenic carcinoma. If the malignant cells in the sputum possess no distinctive features the primary or secondary nature of the tumor must be assessed in the light of the whole clinical picture.

Small cell bronchogenic carcinoma.—Exfoliated carcinoma cells from a small cell bronchogenic carcinoma are readily detected by the smear technique. The cells are small in size as compared with carcinoma cells of other types but nevertheless stand out prominently under the low power objective, frequently in clusters or streaks across the slide. Occurring in this fashion they are readily detected under

low magnification whereas a single cell might escape notice. Under the high power objective the main features of note are the small size of the cells, the virtual absence of cytoplasm and the hyperchromatism of the nuclei (Fig. 3a). Definite variation in size of the nuclei from cell to cell is a very important criterion in diagnosis. The nuclear chromatin forms a coarse network. Nucleoli are usually not prominent in carcinoma cells of this type. The appearance of the cells in tissue sections of this type of bronchogenic carcinoma is shown in Figure 3b.

Undifferentiated bronchogenic carcinoma.—Carcinoma cells in sputum from an undifferentiated bronchogenic carcinoma with corresponding tissue section are shown in Figure 3c and d. In such cases the carcinoma cells are large with marked variation in size and shape of the nuclei. The nucleus is large in relation to the cytoplasm, is hyperchromatic and contains prominent nucleoli. Cells of this type occurring singly as shown here provide adequate evidence for a diagnosis of carcinoma. Clumps of carcinoma cells although not essential aid greatly in the case of diagnosis.

A clump of cells from an undifferentiated bronchogenic carcinoma is shown in Figure 4a. These cells exhibit all the characteristics of malignancy seen in a tissue section (except invasion) including large size, marked variation in size and shape of nuclei, hyperchromatism and very large nucleoli.

Squamous cell carcinoma.—Exfoliated cancer cells from a squamous cell bronchogenic carcinoma are shown in Figure 3e and a corresponding tissue section is shown in Figure 3f. In this type the carcinoma cells are large with irregularity in size and shape of the nuclei. The cytoplasm is frequently abundant and is deeply eosinophilic depending on the degree of keratinization of the cells (Fig. 4b). Inclusion of one cell in another suggestive of a beginning whorl or cell nest is a rather frequent finding (Fig. 4c). As is true of small cell carcinoma, the cytologic characteristics of sputum from a patient with a keratinizing squamous cell carcinoma is usually distinctive enough to predict accurately the histologic type of tumor to be found in the bronchus.

Adenocarcinoma.—In Figure 5a is shown a clump of neoplastic cells in a bronchial aspiration which exhibit a tendency toward an acinar arrangement. The tissue section in this case revealed an adenocarcinoma of the bronchus (Fig. 5b). The occurrence of such a large fragment of tissue showing a glandular arrangement is distinctly unusual in sputum or bronchial secretions. Occasionally however an abnormal vacuolation of the cytoplasm indicating the production of mucus points to a diagnosis of adenocarcinoma. In most cases of adenocarcinoma a diagnosis of carcinoma cells present is made without any indication of type.

Alveolar cell carcinoma.—In 2 cases in this series atypical cells were found in the sputum and the roentgenologic appearances were those of alveolar cell carcinoma involving both lungs. No tissue was obtained in either of these cases. In a third case one lobe only was involved. The sputum contained carcinoma cells (Fig. 5c). Bronchoscopic examination gave negative results. The excised lobe was diffusely involved with alveolar cell carcinoma (Fig. 5d).

Metastatic tumor of the lung.—In a few cases in this series, carcinoma cells in the sputum were probably of metastatic origin. In 1 instance bronchial secretions contained large plaques of tumor cells of undifferentiated type. A tumor of the testis had been removed 2 years previously and the growth in the lungs was presumably metastatic. In 1 case the bowel and in another the ovary were considered the primary sources of the tumors. Differentiation of primary from secondary tumor of the lung is usually impossible on the basis of smears although the presence of oat cells or squamous carcinoma cells in the sputum represents fairly good evidence of a primary bronchogenic carcinoma.

ANALYSIS OF CASES

This study is based on 150 cases in which carcinoma cells were found in sputum or bronchial secretions. It does not represent the findings in a consecutive series of 150 bronchogenic carcinomas. An exact statistical study was not attempted since secretion or sputum was not available in all cases and in

Fig. 5. Adenocarcinoma of the bronchus and alveolar cell carcinoma of the lung (hematoxylin and eosin stain). a, Carcinoma cells in bronchial secretions from a bronchogenic carcinoma of the adenocarcinoma type showing suggestion of gland formation ($\times 640$) and b, tissue section from same lesion ($\times 395$). c, Carcinoma cells in bronchial secretions ($\times 640$) and, d, tissue section from an alveolar cell carcinoma of the lung ($\times 665$).

some instances the material submitted for examination was inadequate. The method of study adopted was to collect 150 cases in which sputum or bronchial secretion was positive for carcinoma cells and by an analysis of these cases to evaluate the accuracy of the method and its usefulness as a routine diagnostic procedure.

Source of carcinoma cells in sputum. The majority of cases in this series represented proved or suspected bronchogenic carcinoma. In 146 of 150 cases the source of the malignant cells was believed to be a tumor of the bronchus. Carcinoma cells however may appear in the sputum from a malignant lesion anywhere in the respiratory tract pharynx or esophagus. In 2 cases in this series the sputum contained malignant cells arising from an esophageal carcinoma. In both a tracheoesophageal fistula was demonstrated and the na-

ture of the lesion proved by biopsy. In 1 case the trachea and in another the larynx were found to be the source of the carcinoma cells found in the sputum. The latter patient gave a history of several months hoarseness with recent slight hemoptysis. Biopsy revealed a squamous cell carcinoma of the larynx. One disadvantage of sputum examination is this failure to localize the lesion. In contrast to examination of sputum examination of bronchial secretions has the advantage that the source of the malignant cells particularly the side involved can be more accurately determined.

Comparison of sputum and bronchial secretions. A comparison of sputum and bronchial secretions as a source of carcinoma cells reveals no essential advantage of one over the other. In a given case of bronchogenic carcinoma the specimen of sputum submitted may

occasionally be negative for carcinoma cells while the bronchoscopically removed secretions prove positive. This was found to be true in 10 cases of a total of 110 cases of bronchogenic carcinoma in which the sputum was examined. The reverse (sputum positive and bronchial secretions negative for carcinoma cells) was found to be true in 6 of 80 cases in which bronchial secretions were examined. A negative result on sputum examination in a case believed clinically to be carcinoma should be followed by a second and if necessary a third sputum examination. This assures an adequate sampling of the sputum and greatly reduces the possibility of a false negative report. If bronchial secretions submitted in a suspected case of bronchogenic carcinoma are negative for carcinoma cells subsequent examination of the sputum should be carried out. If the results of sputum examination prove positive while the results of examination of bronchial secretions are negative it is assumed that the secretions were not aspirated from the bronchus involved by the carcinoma. Both methods of examination should be utilized whenever possible.

Accuracy of diagnosis. In this series of 146 cases of suspected pulmonary neoplasm a final diagnosis of primary bronchogenic carcinoma was established by bronchoscopic biopsy in 64 cases and by surgical exploration in 24 cases. In 2 additional cases in which the results of bronchoscopic biopsy were positive the pulmonary lesion was considered metastatic. Autopsy biopsy of supraclavicular nodes punch biopsy and section of expectorated tissue provided proof of the diagnosis in 7 cases. In 3 cases a false positive report was given on the basis of the findings in the smears; the absence of carcinoma was proved in 2 of these cases at operation and in 1 at necropsy. In the remaining 46 cases carcinoma was not proved by tissue section since tissue was not available. In all 46 cases carcinoma cells were found in the sputum or bronchial secretions. All patients presented symptoms related to the chest and evidence of carcinoma on roentgenologic examination of the lungs.

In 22 of these 46 cases additional evidence of bronchogenic carcinoma was presented in

the finding of clinical or roentgenologic evidence of metastasis. In 8 additional cases a tumor was visualized by the bronchoscopist although positive results at biopsy were not obtained. In 11 cases a diagnosis of inoperable bronchogenic carcinoma was made on the basis of history, clinical findings and roentgenologic evidence in the chest supported by demonstration of carcinoma cells in the sputum. In 1 case the final diagnosis was primary bronchogenic carcinoma or ovarian carcinoma with metastasis to the lungs. In 2 cases the disease was diagnosed alveolar cell carcinoma or metastatic malignant lesions to both lungs. In 1 case of long standing pulmonary suppurative disease roentgenologic findings in the chest were those of extensive cavitation of the upper third of both pulmonary fields. Sputum studies for acid fast bacilli gave negative results but cytologic studies showed numerous carcinoma cells present. Bronchoscopy failed to locate any malignant process. No follow-up on this patient was available. In 1 case the final diagnosis was empyema or bronchogenic carcinoma and no further information could be secured. In all cases except the last 2 the diagnosis of a malignant process in the lung was considered to be beyond doubt. All lesions were considered inoperable or operation was recommended and refused. In the last 2 cases the clinical impression favored a nonmalignant process but atypical cells were found in the sputum smears.

In review of 150 cases in which the smears were reported positive for carcinoma cells, in 145 there was a final diagnosis of carcinoma, in 3 cases the final diagnosis was disease other than carcinoma (proved false positive reports) and the final diagnosis in 2 cases was not established.

Value of the method as an adjunct to established methods of diagnosis. This study indicates that the cytologic study of sputum and bronchial secretion is a valuable adjunct in the diagnosis of bronchogenic carcinoma. Of the 146 patients with suspected bronchogenic carcinoma 114 were examined bronchoscopically. In this group a specimen for biopsy was obtained in 97 cases and the results of biopsy were positive for carcinoma in 66 cases. Thus, of the group of 114 cases in which bron-

Fig 6 Case 1. Peripherally located bronchogenic carcinoma. Lung removed surgically on basis of a, roentgenologic shadow and, b, carcinoma cells in sputum (hematoxylin and eosin stain $\times 640$). c, Lesion indicated by arrow. d, Tissue section (hematoxylin and eosin stain $\times 300$).

choscopy was performed cytologic studies on sputum or bronchial secretions provided the only microscopic basis for a diagnosis of carcinoma in 48 cases (42 per cent).

Surgical exploration was carried out in 58 cases in this series. In 31 of these the results of preoperative bronchoscopic biopsy were

positive while in 25 cases bronchoscopic biopsy could not be performed or the results were negative. Positive results on examination of smears of sputum or bronchial secretions however provided a preoperative diagnosis of carcinoma. In this group two of the three false positive diagnoses were made. In

occasionally be negative for carcinoma cells while the bronchoscopically removed secretions prove positive. This was found to be true in 10 cases of a total of 110 cases of bronchogenic carcinoma in which the sputum was examined. The reverse (sputum positive and bronchial secretions negative for carcinoma cells) was found to be true in 6 of 80 cases in which bronchial secretions were examined. A negative result on sputum examination in a case believed clinically to be carcinoma should be followed by a second and if necessary a third sputum examination. This assures an adequate sampling of the sputum and greatly reduces the possibility of a false negative report. If bronchial secretions submitted in a suspected case of bronchogenic carcinoma are negative for carcinoma cells, subsequent examination of the sputum should be carried out. If the results of sputum examination prove positive while the results of examination of bronchial secretions are negative it is assumed that the secretions were not aspirated from the bronchus involved by the carcinoma. Both methods of examination should be utilized whenever possible.

Accuracy of diagnosis. In this series of 146 cases of suspected pulmonary neoplasm a final diagnosis of primary bronchogenic carcinoma was established by bronchoscopic biopsy in 64 cases and by surgical exploration in 24 cases. In 2 additional cases in which the results of bronchoscopic biopsy were positive the pulmonary lesion was considered metastatic. Autopsy biopsy of supraclavicular nodes punch biopsy and section of expectorated tissue provided proof of the diagnosis in 7 cases. In 3 cases a false positive report was given on the basis of the findings in the smears; the absence of carcinoma was proved in 2 of these cases at operation and in 1 at necropsy. In the remaining 46 cases carcinoma was not proved by tissue section since tissue was not available. In all 46 cases carcinoma cells were found in the sputum or bronchial secretions. All patients presented symptoms related to the chest and evidence of carcinoma on roentgenologic examination of the lungs.

In 28 of these 46 cases additional evidence of bronchogenic carcinoma was presented in

the finding of clinical or roentgenologic evidence of metastasis. In 8 additional cases a tumor was visualized by the bronchoscope although positive results at biopsy were not obtained. In 11 cases a diagnosis of inoperable bronchogenic carcinoma was made on the basis of history, clinical findings, and roentgenologic evidence in the chest supported by demonstration of carcinoma cells in the sputum. In 1 case the final diagnosis was primary bronchogenic carcinoma or ovarian carcinoma with metastasis to the lungs. In 2 cases the disease was diagnosed alveolar cell carcinoma or metastatic malignant lesions to both lungs. In 1 case of long standing pulmonary suppurative disease roentgenologic findings in the chest were those of extensive cavitation of the upper third of both pulmonary fields. Sputum studies for acid fast bacilli gave negative results but cytologic studies showed numerous carcinoma cells present. Bronchoscopy failed to locate any malignant process. No follow-up on this patient was available. In 1 case the final diagnosis was emphysema or bronchogenic carcinoma and no further information could be secured. In all cases except the last 2 the diagnosis of a malignant process in the lung was considered to be beyond doubt. All lesions were considered inoperable or operation was recommended and refused. In the last 2 cases the clinical impression favored a nonmalignant process but atypical cells were found in the sputum smears.

In review of 150 cases in which the smears were reported positive for carcinoma cells, in 145 there was a final diagnosis of carcinoma, in 3 cases the final diagnosis was disease other than carcinoma (proved false positive reports) and the final diagnosis in 2 cases was not established.

Value of the method as an adjunct to established methods of diagnosis. This study indicates that the cytologic study of sputum and bronchial secretion is a valuable adjunct in the diagnosis of bronchogenic carcinoma. Of the 146 patients with suspected bronchogenic carcinoma 114 were examined bronchoscopically. In this group a specimen for biopsy was obtained in 97 cases and the results of biopsy were positive for carcinoma in 66 cases. Thus, of the group of 114 cases in which bron-

has been acquired. Errors at this stage are the result of inexperience of the examiner rather than a result of deficiencies of the method.

After familiarity with the method has been gained, diagnosis by means of smears becomes accurate and reliable.

1 case bronchoscopic examination revealed a tumor projecting from the upper lobe bronchus. Bronchial secretions contained atypical cells interpreted as carcinomatous. Lobectomy revealed stenosis of the upper lobe bronchus with multiple lesions of caseous tuberculosis throughout the lobe. In the second case bronchoscopic examination showed obstruction of the right middle lobe bronchus. Lobectomy was carried out and diffuse bronchiectasis was found in the middle and lower lobes. In the remaining 56 cases in this group bronchogenic carcinoma was demonstrated at operation. In 24 of these cases the lesion proved to be removable. Pneumonectomy or lobectomy for bronchogenic carcinoma was performed on the basis of positive results of bronchoscopic biopsy. In 15 of the 24 cases. In 9 cases bronchoscopic biopsy gave negative results or could not be performed and a preoperative diagnosis of carcinoma was based on the cytologic characteristics of the sputum or bronchial secretions. Of the 9 bronchogenic carcinomas excised on a basis of positive cytologic findings 5 were situated in the upper lobes, 1 in the right middle lobe, 2 in the lower lobes and 1 proved to be an alveolar cell carcinoma diffusely involving the whole left lower lobe of the lung.

Lesions of the upper lobe. Because of the inaccessibility of many upper lobe lesions for bronchoscopic biopsy, study of smears of sputum or bronchial secretions provides an especially useful adjunct to diagnosis in this group. In 19 cases of this series the site of the lesion could not be accurately located. In 41 or almost a third of the remaining cases the lesion was situated in the upper lobes. Diagnosis of bronchogenic carcinoma was established by bronchoscopic biopsy in 12 of these 41 cases. Cytologic diagnosis of carcinoma on the basis of sputum or bronchial secretions was confirmed by surgical exploration in 14 cases and by autopsy, punch biopsy, or lymph node biopsy in 3 additional cases. In 12 cases the dismissal diagnosis was bronchogenic carcinoma, inoperable. In 3 of these 12 cases roentgenologic or clinical evidence of metastasis was present.

Inoperable lesions in the diagnosis of which a bronchoscopic examination is not indicated. In

32 cases of suspected bronchogenic carcinoma, a bronchoscopic examination was not carried out. In these cases roentgenologic or clinical evidence of metastasis, pleural effusion, or other signs of inoperability were presented. In such cases sputum examination provides a convenient method of confirming the clinical diagnosis of bronchogenic carcinoma. A sputum examination the results of which are negative or inconclusive in the face of good clinical evidence of carcinoma should be repeated several times if necessary. In 1 case in this series carcinoma cells were found in the fourth specimen of sputum examined. The diagnostic importance to be attached to negative results on examination of sputum or bronchial secretion depends on the situation of the lesion. In general a hilar lesion associated with repeatedly negative results on sputum examination is almost certainly not carcinoma. A very peripherally located bronchogenic carcinoma may or may not be associated with malignant cells in the sputum depending on the accessibility of the desquamated cells to the bronchial tree.

False positive results of examination of sputum or bronchial secretions. In this series a false positive report on the basis of smears was given in 3 cases. In 2 additional cases the final diagnosis was not established. In 2 of the 3 cases in which proved false positive results were obtained lobectomy was performed. In 1 case bronchial stenosis and caseous tuberculosis were found. In the second, bronchiectasis of the middle and lower lobes was present. In the third case roentgenograms of the lungs revealed a diffuse process in the bases of both lungs which was believed to be inflammatory. Cytologic examination of the sputum disclosed atypical cells interpreted as carcinoma cells. At autopsy extensive pulmonary infarction was found in addition to an organized pneumonic process in both lungs. The mucosa of the large bronchi was the site of squamous metaplasia and marked epithelial proliferation, with numerous mitotic figures in the hyperplastic epithelial cells.

Erroneous diagnoses may occur with this technique in the early period of investigation before sufficient experience with the method

REPORT OF ILLUSTRATIVE CASES

CASE. *Peripheral bronchogenic carcinoma.* A 39 year old white man complained of fever, malaise, night sweats, and weight loss of 1 month duration. Symptoms relating to his chest were minimal consisting of slight hemoptysis and pain in the left axilla for 3 days before admission. Results of roentgenologic examination of the chest (Fig 6a) were reported as follows: Pathologic process left apex, probably tuberculosis but rule out primary malignancy. Bronchoscopic examination gave negative results. The sputum was negative for acid-fast bacilli and fungi. Clinically the picture did not suggest malignancy but had many features of an infectious process. The skin test and serum agglutination test were positive but blood cultures were negative for Brucella. The problem was solved by a cytologic examination of sputum which showed carcinoma cells (Fig 6b). The lung was resected and small lesion was found in the apex (Fig 6c) measuring less than 2 centimeters in diameter. In sputum

nancy. Bronchoscopic examination gave negative results. The sputum was negative for acid-fast bacilli and fungi. of its very peripheral location large numbers of carcinoma cells were being discharged in the sputum. Histologically the tumor was a highly undifferentiated bronchogenic carcinoma (Fig. 6d).

CASE 3. Branchogenic carcinoma of the upper lobe. A 56 year old man registered at the clinic because of pain in the right side of the chest and cough of about 4 months duration. Roentgenograms of the chest revealed a mass in the posterior segment of the right upper lobe bronchogenic carcinoma to be ruled out (Fig. 7a). Bronchoscopy was carried out with the following report: "I was unable to get out far enough in the right upper lobe bronchus to visualize a growth. The right upper lobe bronchus seemed to be fixed. Specimen for biopsy could not be obtained. Sputum was negative for acid fast bacilli and fungi but was found to contain many carcinoma cells (Fig. 7b). A right pneumonectomy was performed and pathologic examination disclosed a bronchogenic carcinoma 5 centimeters in diameter involving the bronchus of the right upper lobe (Fig. 7c). Tissue section revealed a squamous cell carcinoma (Fig. 7d). No involvement of the lymph nodes was found.

CASE 3. Peripheral bronchogenic carcinoma of the right middle lobe. A 71 year old woman complained of a chronic dry cough of 8 months duration. The patient had had a cough each winter for several years which cleared up each time after the cold weather. Nine months before admission she had had an episode of pain in the lower part of the right side of the chest which extended up under the right scapula. No hemoptysis was noted at any time. The patient felt well and had gained weight. Roentgenograms of the chest (Fig. 8a) revealed thickened pleura with residual fibrosis in the right base. Sputum studies were negative for acid-fast bacilli but cytologic studies were positive for carcinoma cells (Fig. 8b). A bronchoscopic examination was carried out with the following report: "I was unable to visualize any tumor in the right lower lobe." Surgical exploration was done on the basis of the sputum findings and a tumor of the right lung was palpated. Because of the patient's age the surgeon elected to do a middle and lower lobe lobectomy. Pathologic examination revealed a small bronchogenic carcinoma involving one of the bronchi of the right middle lobe (Fig. 8c). Histologic section showed a squamous cell carcinoma (Fig. 8d). The patient had an excellent postoperative course and was discharged in good condition.

CASE 4. Carcinoma in a bronchogenic cyst. A 54 year old white man was admitted to the clinic because of cough, pain in the chest, and hemoptysis of 3 months duration. For the past 6 to 8 months he had noted little by little a loss of 10 pounds (4.5 kgm.) occasional fever and night sweats. His past history revealed several attacks of pneumonia and pleurisy. Sputum examination for acid-fast bacilli and tuberculin skin tests gave negative results. Results of roentgenologic examination of the chest (Fig. 9a) were reported as follows: There is a large, rather

well circumscribed cavity in the left upper lobe without a great deal of surrounding reaction. Some fibrosis in left apex. Rule out bronchogenic carcinoma with cavitation." The story of respiratory difficulty of long duration and the roentgenologic appearance of the lesion strongly suggested a bronchogenic cyst. However an examination of the sputum revealed carcinoma cells in great numbers (Fig. 9b). A bronchoscopic examination was not carried out. The preoperative diagnosis was carcinoma of the left upper lobe with cavitation. A left pneumonectomy was performed and the pathologic examination of tissue removed revealed a squamous cell carcinoma 4 by 3 by 2 centimeters in the wall of a bronchogenic cyst 6 centimeters in diameter (Fig. 9c). Histologic section (Fig. 9d) showed a squamous cell carcinoma. No lymph nodes were found involved. One small bronchus opened into the cyst, providing a pathway for the carcinoma cells to reach the sputum. The postoperative course was uneventful.

COMMENT

This study would indicate that cytologic examination of sputum and bronchial secretions is an extremely valuable adjunct in the diagnosis of carcinoma of the lung. Carcinoma cells may be distinguished from normal cells in the smear by a variety of atypical features including large size variation in size and shape particularly of the nuclei hyperchromatism and large nucleoli. A high degree of accuracy of diagnosis may be accomplished by this method as is shown by the occurrence of only 3 proved false positive reports in 150 cases in which a diagnosis of carcinoma was made by the smear technique.

The interpretation of smears requires considerable experience but, once this is gained, the test has great practical value. In practice a microscopic diagnosis of carcinoma is frequently established within an hour of receiving the specimen at the laboratory. It provides microscopic evidence of malignancy in many cases in which proof is otherwise not obtainable.

Many bronchogenic carcinomas particularly lesions of the upper lobe and peripherally located neoplasms are not accessible for bronchoscopic biopsy. In this series 224 patients underwent bronchoscopic examination. In 17 of these material for biopsy could not be obtained. In 31 cases the tissue removed for biopsy proved to be nonneoplastic while in the remaining 66 cases a microscopic diagno-

sis of bronchogenic carcinoma was made on the tissue removed. Obviously any method which would serve to supplement bronchoscopic examination and provide microscopic proof of the presence of carcinoma when biopsy cannot be performed would be of immense practical importance in the diagnosis of pulmonary neoplasms. It has been shown that cytologic study of sputum and bronchoscopically removed secretions provides this microscopic proof in the majority of these in accessible lesions. By combining both methods in the examination of the patient with suspected bronchial carcinoma a much higher rate of positive diagnoses can be accomplished than heretofore has been the case.

The ability to make a microscopically proved diagnosis of cancer in a higher percentage of cases will serve to reduce materially the pre-operative diagnosis of indeterminate pulmonary lesion. In this series exploration for bronchogenic carcinoma was carried out in a total of 58 cases. Of this number in 31 or 53.4 per cent carcinoma was diagnosed on the basis of bronchoscopic biopsy. In 25 cases cancer cells in the sputum or secretions provided the only microscopic evidence of malignancy. In 2 cases a false positive diagnosis was given on the basis of smears.

Furthermore by use of the smear technique a positive microscopic diagnosis of carcinoma may be made in many cases of suspected bronchogenic carcinoma in which a bronchoscopic examination is not indicated. In 32 cases no bronchoscopic examination was carried out. The demonstration of carcinoma cells in the sputum in these cases was a valuable confirmation of the clinical and roentgenologic evidence of primary bronchogenic carcinoma.

The need for earlier diagnosis of cancer of the lung is shown by the low rate of resectability of these lesions. In this series 24 bronchogenic carcinomas were removed in a total of 143 cases of suspected malignant disease. More widespread use of cytologic examination of sputum for cancer cells offers a hope of earlier detection of bronchogenic carcinoma before the lesion has progressed to an inoperable stage. Because of the vital importance of earlier diagnosis it is felt that every patient with an undiagnosed lesion of the chest

should be given the benefit of a carefully conducted cytologic examination of sputum or bronchial secretions for cancer cells.

SUMMARY

The purpose of this study was the identification of cancer cells in sputum or bronchial secretions and evaluation of the smear technique as a routine procedure in the diagnosis of bronchogenic carcinoma.

The technique employed was based on the original work of Dudgeon and Wringle. Sputum was examined while fresh or it was collected in a few cubic centimeters of 95 per cent alcohol. Five smears were made from each specimen. The smears were fixed while wet in equal parts of absolute alcohol and ether for 30 minutes. The staining method adopted was Harris hematoxylin followed by dilute eosin as a counterstain.

Smears of sputum or bronchial secretions from nonneoplastic diseases of the lung revealed squamous and ciliated columnar epithelial cells, macrophages and various inflammatory cells.

Carcinoma cells in smears could be distinguished from normal cells by numerous atypical characteristics including large size variation in size and shape of the cells and of the nucleus, the nuclear-cytoplasmic ratio, hyperchromatism of the nucleus and the presence of large nucleoli.

The appearance of carcinoma cells in sputum and bronchial secretions varies with the histologic type of tumor in the bronchus. Cancer cells originating in a bronchogenic carcinoma of small cell oat-cell type or in a keratinizing squamous cell type provide the most distinctive morphologic characteristics. A diagnosis of the histologic type of tumor present was usually possible in the case of these two cell types. In most other bronchogenic carcinomas especially the more undifferentiated tumors a diagnosis of carcinoma cells present was made without reference to histologic type.

Metastatic lesions of the lungs may be the source of carcinoma cells in sputum or bronchial secretions.

Analysis of 150 cases in which the smears were diagnosed positive for carcinoma cells

of its very peripheral location large numbers of carcinoma cells were being discharged in the sputum. Histologically the tumor was a highly undifferentiated bronchogenic carcinoma (Fig. 6d).

CASE 2. Bronchogenic carcinoma of the upper lobe. A 56 year old man registered at the clinic because of pain in the right side of the chest and cough of about 4 months duration. Roentgenograms of the chest revealed a mass in the posterior segment of the right upper lobe to be bronchogenic carcinoma to be ruled out (Fig. 7a). Bronchoscopy was carried out with the following report: "I was unable to get out far enough in the right upper lobe bronchus to visualize a growth. The right upper lobe bronchus seemed to be fixed. Specimen for biopsy could not be obtained. Sputum was negative for acid-fast bacilli and fungi but was found to contain many carcinoma cells (Fig. 7b). A right pneumonectomy was performed and pathologic examination disclosed a bronchogenic carcinoma 5 centimeters in diameter involving the bronchus of the right upper lobe (Fig. 7c). Tissue section revealed a squamous cell carcinoma (Fig. 7d). No involvement of the lymph nodes was found."

CASE 3. Peripheral bronchogenic carcinoma of the right middle lobe. A 71 year old woman complained of a chronic dry cough for 8 months duration. The patient had had a cough each winter for several years which cleared up each time after the cold weather. Nine months before admission she had had an episode of pain in the lower part of the right side of the chest which extended up under the right scapula. No hemoptysis was noted at any time. The patient felt well and had gained weight. Roentgenograms of the chest (Fig. 8a) revealed "thickened pleura with residual fibrosis in the right base. Sputum studies were negative for acid fast bacilli but cytologic studies were positive for carcinoma cells (Fig. 8b). A bronchoscopic examination was carried out with the following report: "I was unable to visualize any tumor in the right lower lobe. Surgical exploration was done on the basis of the sputum findings and a tumor of the right lung was palpated. Because of the patient's age the surgeon elected to do a middle and lower lobe lobectomy. Pathologic examination revealed a small bronchogenic carcinoma involving one of the bronchi of the right middle lobe (Fig. 8c). Histologic section showed a squamous cell carcinoma (Fig. 8d). The patient had an excellent postoperative course and was dismissed in good condition."

CASE 4. Carcinoma of a bronchogenic cyst. A 54 year old white man was admitted to the clinic because of cough, pain in the chest, and hemoptysis of 2 months duration. For the past 6 to 8 months he had noted listlessness, loss of 10 pounds (4.5 kgm.), occasional fever and night sweats. His past history revealed several attacks of pneumonia and pleurisy. Sputum examination for acid-fast bacilli and tuberculin skin tests gave negative results. Results of roentgenologic examination of the chest (Fig. 9a) were reported as follows: "There is a large, rather

well circumscribed cavity in the left upper lobe without a great deal of surrounding reaction. Some fibrosis in left apex. Rule out bronchogenic carcinoma with cavitation." The story of respiratory difficulty of long duration and the roentgenologic appearance of the lesion strongly suggested a bronchogenic cyst. However an examination of the sputum revealed carcinoma cells in great numbers (Fig. 9b). A bronchoscopic examination was not carried out. The preoperative diagnosis was carcinoma of the left upper lobe with cavitation. A left pneumonectomy was performed and the pathologic examination of tissue removed revealed a squamous cell carcinoma 4 by 3 by 2 centimeters in the wall of a bronchogenic cyst 6 centimeters in diameter (Fig. 9c). Histologic section (Fig. 9d) showed a squamous cell carcinoma. No lymph nodes were found involved. One small bronchus opened into the cyst, providing a pathway for the carcinoma cells to reach the sputum. The postoperative course was uneventful.

COMMENT

This study would indicate that cytologic examination of sputum and bronchial secretions is an extremely valuable adjunct in the diagnosis of carcinoma of the lung. Carcinoma cells may be distinguished from normal cells in the smear by a variety of atypical features including large size, variation in size and shape particularly of the nuclei, hyperchromatism and large nucleoli. A high degree of accuracy of diagnosis may be accomplished by this method as is shown by the occurrence of only 3 proved false positive reports in 150 cases in which a diagnosis of carcinoma was made by the smear technique.

The interpretation of smears requires considerable experience but, once this is gained, the test has great practical value. In practice a microscopic diagnosis of carcinoma is frequently established within an hour of receiving the specimen at the laboratory. It provides microscopic evidence of malignancy in many cases in which proof is otherwise not obtainable.

Many bronchogenic carcinomas, particularly lesions of the upper lobe and peripherally located neoplasms, are not accessible for bronchoscopic biopsy. In this series 114 patients underwent bronchoscopic examination. In 17 of these material for biopsy could not be obtained. CLINICAL RESPONSE OF METASTATIC LESIONS OF CARCINOMA OF THE FEMALE BREAST TO HORMONAL THERAPY AS RELATED TO HISTOLOGIC GRADE OF MALIGNANCY

ELIZABETH LOWENHAUPT, M.D. and HOWARD L. STEINBACH, M.D.
San Francisco, California

HORMONAL therapy is a recognized method of control of remote lesions in carcinoma of the female breast (2). The clinical response is not uniform and various factors have been cited as influencing the prognosticated response. Thus Nathanson states in regard to stilbesterol that favorable responses are confined to older women and that in younger women the disease is unaltered or perhaps accelerated. Halberstaedter and Hochman report that typical adenocarcinomas are more susceptible to treatment with estrogens than are anaplastic tumors. Their conclusion however is based on pathologic reports with no uniform terminology and no attempt at detailed grading. For these reasons it seems of interest to correlate histologic evidence of growth rate (and by inference physiologic maturity) with the observed response to physiologic modes of treatment.

MATERIAL AND METHODS

Clinical material and therapeutic methods are described in a report by one of the authors (HLS 8). All cases of this report in which histologic material was available are included here. These cases 27 in all 17 treated with estrogens and 10 with testosterone are summarized in Tables I and II.

Without being aware of the clinical data one of us (EL) reviewed all of the sections and graded¹ the tumor according to the criteria

shown by Greenough to be of prognostic worth. This author has shown the following five points to be evidence of low malignancy: (1) marked adenomatous pattern (2) marked secretion by cells (3) uniformity of cell appearance and size (4) uniformity of nuclear size and (5) lack of nuclear hyperchromatism and of mitotic figures. Accordingly the maximum of each category was given the grading four plus and the minimum zero the five averaged and the tumor assigned to an arbitrary group: low malignancy three plus or over medium two plus and high one plus or less—using the nearest whole figure. This material is summarized with the clinical data in Tables I and II. Examples of each of these groups are shown in Figures 1 to 6.

RESULTS

The large percentage of tumors of high malignancy in this series does not represent carcinomas of the breast in general; those of lower grades are probably cured by radical surgery. Thus this represents a distortion. However in this series although most carcinomas in younger age groups are highly malignant the reverse is not true contrary to accepted belief (3). As shown in Figure 7 there were 5 highly anaplastic tumors after 60 years. This is of importance in determining the type of treatment; the decision at present being made primarily on clinical data. This will be discussed below.

In summarizing it was found that because of its use in the young age group in most of the patients receiving testosterone the tumors were of high malignancy (8). Of these only one responded; the growth remaining temporarily stationary. The tumors in 2 patients showing clinical improvement (O.S. and

Histologic grading, 1. be sure, is at best an approximation and sort of average of many field sections. However it soon becomes evident that each tumor, although not uniform, tends to fit into one class. The two extremes are well separated, though there is, of course, some overlap in the central group. This is brought out in Figures 1 through 6. In very few instances the tumor in the lymph node differed in degree of malignancy from the primary in which instances the grading of the metastasis as considered representing the lesion under treatment.

was carried out. In 146 of these cases the source of the atypical cells was believed to be a tumor in the bronchial tree. In 141 of the 146 cases a final diagnosis of primary or metastatic carcinoma of the lung was made. In 3 cases diagnoses made on the basis of smears were proved to be false positives. In 2 cases the final diagnosis whether inflammatory or neoplastic was not definitely established.

Carcinoma cells in sputum or bronchial secretions provided the only preoperative microscopic evidence of cancer in 25 (43 per cent) of a total of 58 cases in this series in which surgical exploration was carried out.

Of 24 cases of bronchogenic carcinoma in which the lesion could be removed cancer cells in the smears provided the only microscopic evidence of cancer in 9 cases (37 per cent).

CLINICAL RESPONSE OF METASTATIC LESIONS OF CARCINOMA OF THE FEMALE BREAST TO HORMONAL THERAPY AS RELATED TO HISTOLOGIC GRADE OF MALIGNANCY

ELIZABETH LOWENHAUPT, M.D., and HOWARD L. STEINBACH, M.D.,
San Francisco, California

HORMONAL therapy is a recognized method of control of remote lesions in carcinoma of the female breast (2). The clinical response is not uniform and various factors have been cited as influencing the prognosticated response. Thus Nathanson states in regard to stilbesterol that favorable responses are confined to older women and that in younger women the disease is unaltered or perhaps accelerated. Halberstaedter and Hochman report that typical adenocarcinomas are more susceptible to treatment with estrogens than are anaplastic tumors. Their conclusion however is based on pathologic reports with no uniform terminology and no attempt at detailed grading. For these reasons it seems of interest to correlate histologic evidence of growth rate (and by inference physiologic maturity) with the observed response to physiologic modes of treatment.

MATERIAL AND METHODS

Clinical material and therapeutic methods are described in a report by one of the authors (HLS 8). All cases of this report in which histologic material was available are included here. These cases 27 in all 17 treated with estrogens and 10 with testosterone are summarized in Tables I and II.

Without being aware of the clinical data one of us (EL) reviewed all of the sections and graded¹ the tumor according to the criteria

shown by Greenough to be of prognostic worth. This author has shown the following five points to be evidence of low malignancy: (1) marked adenomatous pattern (2) marked secretion by cells (3) uniformity of cell appearance and size (4) uniformity of nuclear size and (5) lack of nuclear hyperchromatism and of mitotic figures. Accordingly the maximum of each category was given the grading four plus and the minimum zero the five averaged and the tumor assigned to an arbitrary group: low malignancy three plus or over medium two plus and high one plus or less—using the nearest whole figure. This material is summarized with the clinical data in Tables I and II. Examples of each of these groups are shown in Figures 1 to 6.

RESULTS

The large percentage of tumors of high malignancy in this series does not represent carcinomas of the breast in general; those of lower grades are probably cured by radical surgery. Thus this represents a distortion. However in this series although most carcinomas in younger age groups are highly malignant the reverse is not true contrary to accepted belief (3). As shown in Figure 7 there were 5 highly anaplastic tumors after 60 years. This is of importance in determining the type of treatment; the decision at present being made primarily on clinical data. This will be discussed below.

In summarizing it was found that because of its use in the young age group in most of the patients receiving testosterone the tumors were of high malignancy (8). Of these only one responded; the growth remaining temporarily stationary. The tumors in 2 patients showing clinical improvement (O.S. and

				Cell	Nucleus			
1	B	—	++	++	+	—	Low	Improved with testosterone
2	I. W.	++	—	+++	—	+++	Low	Improved with estrogen (adjuvant therapy)
3	M. R.	+	—	—	—	+++	Medium	Wks. nodes deep with estrogen. No response
4	F. T.	—	—	—	—	++	Medium	Pain not severe, no change in axillary mass
5	M. W.	—	++	+	+	—	High	Lesions progress with estrogen
6	F. W.	—	—	+	+	—	High	Lesions progress with estrogen

BS) were of medium and low malignancy. The improvement in these patients refers to osseous metastases (8) and this will be discussed further below.

A similar trend was found in respect to the patients treated with estrogens. Thus the 2 patients with tumors of low malignancy improved, 5 of the 8 of medium and only 1 of the 7 of high grading. The results for the whole series are shown graphically in Figure 8.

DISCUSSION

Testosterone the substance of choice in young women (1, 7, 8) and of use in control of osseous metastases (1) acts by way of its effect on calcium metabolism (1) showing under still living tumor cells. It is to be expected and is borne out by this series, that more slowly proliferating tissue would be more effectively buried in new forming bone. Those tumors of high malignancy predicted as non-

Fig. 7 Malignancy as related to age and to clinical response. Tumors in young women are in general of high malignancy and there is a gradual fall with advancing age. However 3 tumors of high malignancy occurred here in women over 60 years. Also shown is the fact that only 1 tumor of high malignancy improved with hormonal therapy while only 1 of medium or low malignancy progressed.

responsive might well receive concomitant roentgen therapy to local bone lesions (8)

Estrogens of use in older women (7, 8) are effective in control of metastatic soft tissue lesions of low and low medium malignancy (Figs 1 to 6). The decision as to treatment, then, cannot be made on the basis of age alone for highly malignant tumors are present in old women (Fig 7 F W, aged 76). These soft

Fig. 8. Response of all hormone treated carcinomatous metastases as related to degree of malignancy

tissue lesions will not be controlled by estrogens and might well receive concomitant x ray therapy from the outset or as symptoms occur (8). It is a matter of conjecture as to the effect of testosterone on bone lesions in elderly people with osteoporotic skeletal systems in which anaplastic cells are proliferating.

Of interest is the history of a long period of cure, with late recurrence of remote lesions of medium malignancy (16 years in the case of M Ro 17 years in the case of M Ra). It seems likely that the original metastatic cells

+ = plus

may well have been of slow growth rate, or quiescent, with only recent, more rapid growth and perhaps change of histologic pattern perhaps in a changing environment.

SUMMARY

Response of remote metastases of carcinoma of the female breast to hormonal therapy is correlated with the histologic grade of malignancy. Tumors of low grade responding most favorably. Degree of malignancy cannot be predicted on the basis of age. It is suggested that information obtained by biopsy examina-

tion be used as an additional factor in determining the clinical management of each patient.

THE 'VERTICAL EPIDEMIC' OF MAMMARY CARCINOMA IN MICE

Its Possible Implications for the Problem of Cancer in General

LUDWIK GROSS M.D., New York, New York

OBSERVATIONS have been made recently on mouse mammary carcinoma which may fundamentally influence our approach to the problem of cancer in general. These observations can be summarized as follows:

There exist families of mice in which in each successive generation, practically all middle aged females develop mammary carcinomas (48, 26 50, 51 52, 9 11 4 5). These animals are for all practical purposes in perfect health during their early adult age although they are earmarked to die from cancer. They develop tumors upon reaching approximately one to one and a half years of age. The causative agent responsible for the development of breast cancer is transmitted in these tumor families of mice from one generation to another through the milk of nursing mothers (10, 14, 17, 1).

A SIMPLE METHOD OF PREVENTING BREAST CANCER IN MICE

The development of mammary carcinomas in otherwise susceptible mice of the tumor families can be prevented by the simple measure of isolating the newly born animals from their tumor agent carrying mothers and transferring them for the purpose of nursing to females whose milk is free from the invisible mammary carcinoma agent. Such foster nursed animals grow up and remain healthy despite the fact that they are direct descendants of a tumor family. They live their normal life spans and do not develop breast tumors. Moreover, their milk is also free from the tumor agent, they can, in due time, nurse their own litters naturally, without transmit-

ting to them the seed of the fatal disease (10, 14 17, 1).

On the other hand, female mice that belong to families free from mammary carcinoma, can be infected with the invisible tumor agent by ingesting, in early infancy milk containing the mammary carcinoma factor. The infection can be accomplished experimentally by placing such newly born mice under the care of a foster mother whose milk contains the tumor factor. Such infected animals grow up and remain apparently healthy, they harbor however, the tumor agent and transmit it to their progeny. When these animals reach the tumor age they develop and eventually die from mammary carcinomas. In the meantime however, their progeny has grown up, and has, in turn transmitted the tumor agent to the next succeeding generation.

BIOLOGICAL PROPERTIES OF THE TUMOR AGENT

The mammary carcinoma agent present in the milk of females of certain high tumor lines of mice earmarked to develop breast tumors later in life is so small as to be invisible under an ordinary, optical microscope. The agent is filterable through a bacteria tight Seitz filter (19 7).

The agent is present not only in the milk of female mice earmarked to develop mammary carcinomas, but also in the tumor cells (15). When such tumors are transplanted by graft, from one animal to another they carry with them the tumor agent which can later be extracted from such tumors after several successive transplantations (21). The agent is present in the mammary tissue (13, 6) of mice earmarked to develop mammary carcinomas less constantly in certain organs of such animals (12, 6) and occasionally also in their blood (59). The simplest method of obtaining the agent is to grind a mammary tumor, whether

Fig The spread of mammary carcinoma following exposure, that is, the ingestion of milk containing the tumor agent.

spontaneous or transplanted, with physiological sodium chloride solution and then separate the agent from the tumor cells by centrifugation at low speed. The agent is present in the supernatant fluid. A few drops of such a fluid fed to newly born mice by an eye dropper or a simple feeding device (40) will result in the development of spontaneous mammary carcinomas in these animals a year and a half later. In the meantime however these animals will have already transmitted the agent, through milk, i.e. naturally to their own progeny.

Oral administration of the agent is effective, and results in the eventual development of tumors, provided the animals ingest the virus in early infancy i.e. when 1 to 28 days of age. Feeding of adult or middle aged animals with either milk or extracts from tissues containing the tumor agent, results occasionally only if at all, in the development of mammary carcinomas (6 20). Subcutaneous or intraperi-

toneal (7) injection of the agent into young animals is an excellent means of producing experimentally spontaneous mammary carcinomas when older animals, however are injected, they will develop tumor much less frequently or not at all (3 6 20 23) unless massive doses of the virus are inoculated (23).

The tumor agent is destroyed by heating to 61 degrees C. for 30 minutes. Thus, the agent would not resist pasteurization (7 8).

The tumor agent has antigenic properties (7 31). Following injection of the agent (i.e. a mouse mammary carcinoma extract) into a rabbit, no tumors, of course develop in these animals. The serum of such a rabbit, however acquires the property of neutralizing the agent in vitro. When such an immune serum is incubated, in a test tube, at room temperature, for 2 hours with mouse mammary carcinoma agent, it neutralizes it. The mixture injected into mice will not produce tumors. The neutralization is specific. Normal rabbit serum, for instance, will not neutralize the tumor agent (7 31) neither will the mammary carcinoma agent be neutralized by a serum obtained from a rabbit that had been injected with a different tumor (7) or with normal mouse organs (31).

The various biological properties of the mouse mammary carcinoma agent discussed above appear to suggest that this agent is a virus.

MAMMARY CARCINOMA OF MICE— A COMMUNICABLE DISEASE

Thus, in mice at least, mammary carcinoma can be acquired in early infancy by ingestion of an extraneous transmissible agent. Once acquired the disease is self propagating from one host to another through the milk of nursing females. The chain of transmission of mammary carcinoma in a family of mice can be interrupted, however by isolating the newly born animals from their potentially cancerous mothers and preventing them from ingesting the tumor agent. In other words, mouse mammary carcinoma can be acquired by exposure (Fig 1). Once acquired, it becomes self perpetuating from one host to another. The acquisition of the disease can be prevented however by isolation (Fig 2).

Upon reviewing these facts dispassionately, it is difficult to avoid the conclusion that breast cancer of mice is a communicable disease (33)

THE VERTICAL PATTERN OF TRANSMISSION OF MOUSE MAMMARY CARCINOMA AGENT

When comparing the pattern of transmission of mammary carcinoma of mice with that of many common communicable diseases, several differences become apparent. In the case of measles, smallpox or typhoid fever, the transmission of the infectious agent occurs among hosts that, in most instances at least belong to the same generation thus an infected host placed in close quarters with other, healthy, but susceptible individuals of practically any age will often transmit the infecting agent to its companions. In the case of mouse mammary carcinoma, however the causative agent is as a rule transmitted among hosts belonging to successive generations. A mouse carrying the tumor agent and bearing a large exposed perhaps already ulcerated mammary carcinoma can be placed in the same cage with healthy susceptible mice yet, no transmission of the disease will result. The same tumor bearing mouse, however, will transmit the tumor agent, through milk, to her own daughters, and through these to her granddaughters, great granddaughters, and so forth i.e. to hosts of successive generations. The term vertical epidemic has been suggested for this type of transmission of extraneous parasitic agents (33)

In mouse mammary carcinoma the exposure and infection occur early in infancy. This is followed by apparent health lasting at least through the early adult life of the host during that time the disease spreads to the next group of hosts which belongs to the next succeeding generation. The symptoms of the disease (tumors) appear in most instances at the end of the life cycle of the host, i.e. after the transmission of the causative agent has been assured this is followed by death of the host. Thus we have (1) exposure and infection followed by (2) a very long asymptomatic phase of apparent health coupled with (3) the ability of the host to transmit the disease

Fig. 2. Arresting the vertical transmission of mammary carcinoma in mice by isolation, that is foster nursing, preventing the ingestion of milk containing the tumor agent.

to other individuals and finally (4) appearance of symptoms of disease, and (5) death of the host.

This pattern is essentially different from that observed in the majority of common communicable diseases where, following (1) exposure and infection (which may occur at almost any time during the life cycle of the host) very promptly (2) symptoms of the disease appear coupled with (3) the simultaneous ability of the host to transmit the infectious agent to other susceptible individuals belonging as a rule to the same generation (4) either death or recovery of the host follows.

THE SKIPPING OF GENERATIONS IN THE TRANSMISSION OF MOUSE MAMMARY CARCINOMA

Despite these differences there are certain common traits between these two patterns. Both groups of diseases are caused by extraneous parasitic agents. In both instances an individual may harbor the agent and actually

follow the actually continuous, though at times inapparent, chain of transmission of the causative tumor agent. If complete records are on hand, the pattern of transmission becomes at once evident. It then becomes clear that each case of mammary carcinoma can in these animals be traced to another similar case of the same disease. The law of obligate communicability (Fig. 4) long established for other infectious diseases, becomes then evident also for mammary carcinoma of mice (33).

THE TRANSMISSIBLE INACTIVE FORM OF THE TUMOR AGENT AND ITS DELAYED ACTIVATION IN THE HOST

Among the many questions which immediately present themselves, one of the most striking is that concerning the very long interval of time which passes between the exposure of the host to the transmissible agent (early in fancy) and the actual appearance of symptoms of the disease, i.e. the formation of the tumor.

It appears possible to assume that the invisible tumor agent is transmitted from one animal to another in some inactive form and that it remains inactive and harmless during most of the life span of its host. Usually at the end of the host's life cycle conditions may develop which at least in some instances, may prompt an activation of the hitherto inactive tumor agent. The conditions favoring such activation have not yet been fully determined, and are poorly understood at least some of these conditions however are known, as for example old age or certain hormonal stimulations.

Upon activation of the tumor agent, a new growth develops at the site of the activation, i.e. locally in the cells where the agent was harbored and where activation actually occurred. From then on the activated agent causes the cells to multiply at the point of activation. The tumor then grows rapidly in filtrating the surrounding tissues not unlike any local infection. It may also spread through the lymphatic channels into either adjoining groups of lymph glands or apparently through migrating tumor cells it may form distant metastases.

Fig. 4. The vertical epidemic of cancer. (1) This is not inheritance, but a vertical transmission of an extraneous parasitic agent. (2) The agent is communicable from one individual to another of successive generations. (3) Many carriers transmit the virus but never show any symptoms of disease.

THE ACTIVATION OF TUMOR AGENT IS LOCAL

It is possible to assume that only a small fraction of the agent, which is harbored by the host, becomes at one time activated, forming a new growth and that the activation is thus a purely local phenomenon. The remaining inactive agent, harbored elsewhere by the same host, may not become activated at the same time. Thus a host that bears a tumor (caused by an activated agent) may harbor in addition, in other, apparently healthy tissues the remaining inactive tumor agent. At a later date, however, should the host survive for a prolonged period of time additional new activations of the tumor agent may occur at new sites forming new primary tumors. This would explain the commonly observed fact that spontaneous mammary carcinomas may develop successively in several different mammary glands in a mouse. Conditions favoring the initial activation may either persist or again develop causing successive appearance of several similar tumors. The activation theory would perhaps explain why tumors that appear to develop only in middle aged or old animals once they develop will grow indiscriminately upon transplantation, in either old or young hosts. Thus it is not a resistance of the young animal to the tumor, but the lack of an active tumor agent that is responsi-

ble for the absence of spontaneous mammary carcinomas in youth and early adult age. Once activated however the tumor seems to be equally capable of growing when transplanted in susceptible hosts of any age (32)

THE VERTICALLY TRANSMITTED PARASITIC AGENTS IN INSECTS AND PLANTS

There exist many communicable diseases which are transmitted vertically and which in principle at least, follow the pattern observed in mammary carcinoma of mice. The Rocky Mountain spotted fever rickettsiae (49) or the tularemia organisms (41) (Fig 5) for instance are transmitted in the tick through the eggs of these insects from one generation to another i.e. vertically. The

horizontal transmission of these organisms that is a transmission between insect hosts belonging to the same generation is possible when an intermediary host such as man for instance intervenes. In the absence of a suitable intermediary host, however only vertical transmission occurs. Many other communicable diseases of insects exist that are known to be transmitted from one generation to another vertically (49 41 42 27 29) not unlike mammary carcinoma of mice.

Similar observations have been made on plants. Thus, it was observed that certain diseases of plants, caused by extraneous filterable viruses, are transmitted from one plant to another through the seeds. An infected plant may grow next to a healthy one and yet no transmission of the disease will occur among hosts belonging to the same generation. However the infected plant will transmit the virus through the seeds or in the case of mosaic disease of the potato through the tubers, to the next generation. The transmission through the seeds or through the tubers, from one generation to another is essentially a "vertical" transmission of the parasitic agent, fundamentally similar to that observed in mammary carcinoma of mice (Fig 6) The same is true for the mosaic disease of lettuce, tomatoes or certain other plants (30 38)

The vertically transmitted parasitic agents can readily escape detection, particularly when such parasites are invisible, and when they do not always cause symptoms of disease.

The detection becomes somewhat easier in experiments conducted on hosts having a relatively short life span and a rapid reproduction cycle under such experimental conditions the actual host to-host transmission of the pathogenic agents can be more readily followed by the human observer. Even in such instances, however the difficulties are great, and great patience is required.

VERTICAL EPIDEMIC IS NOT TO BE CONFUSED WITH HEREDITY

At first sight vertical transmission may be perhaps confused with inheritance. Upon observing a disease appearing successively in different descendants of the same family a casual observer may be tempted to consider it to be caused by some inherited genetic factor. And yet inheritance and vertical transmission are fundamentally different phenomena. A vertically transmitted mammary carcinoma is actually caused by a host to-host transmission of an extraneous, acquired, parasitic agent. The same is true for mosaic disease of plants or certain vertically transmitted virus diseases of insects.

Inheritance on the other hand, is neither acquired nor is it caused by extraneous, parasitic agents.

IMPORTANCE OF SUSCEPTIBILITY IN THE DEVELOPMENT OF MOUSE MAMMARY CARCINOMA AS COMPARED WITH OTHER COMMUNICABLE DISEASES

The proper susceptibility of the host to the disease-causing agent is obviously fundamental in the development of mammary carcinoma of mice. This factor however is equally important in other communicable diseases, since pathogenic micro-organisms or viruses can act only on susceptible hosts. Plague for instance, is highly dangerous for man and certain rodents, but harmless for chickens. The susceptibility of man to plague is inherited and yet, no one would state that plague, in man is caused by (a) the plague bacillus and (b) inherited susceptibility of man the plague bacillus only would be mentioned as the causative agent, since it goes without saying that this micro-organism will produce disease only in a susceptible host.

Fig 5 Vertical transmission of tularemia in tick following exposure that is, feeding on a host infected with tularemia.

It is true that some mice are more others less susceptible to the tumor agent and that such a susceptibility is inherited. This fact however would not surprise an epidemiologist. Thus field mice are relatively resistant to streptococci or pneumococci whereas albino mice are very susceptible to these organisms (28) by inbreeding of either susceptible or nonsusceptible parents two different lines of mice were obtained by Webster one showing 95 per cent mortality and the other only 5 per cent under the same conditions of exposure to the *Bacillus enteritidis* (57).

The importance of inherited susceptibility in the acquisition and development of mammary carcinoma should be viewed in its proper perspective and should be neither overemphasized nor misinterpreted. The susceptibility of the host which is essentially inherited seems at least in principle no more important in the origin of mammary carcinoma than it is in the acquisition of diseases caused by various micro-organisms and viruses (33).

Fig 6 Vertical transmission of mosaic virus in the potato following exposure. A plant louse (potato aphid) infected with mosaic virus fed on leaf of potato.

NO PEDIGREED INBREEDING NEEDED FOR TRANSMISSION OF MOUSE MAMMARY CARCINOMA

When the initial observations on vertical transmission of mammary carcinoma were made on mice it appeared at first that genetic inbreeding is of paramount importance in such host to-host passage of the tumor agent. It was later observed however that no pedigreed inbreeding is required for such a transmission and that the promiscuous breeding such as exists in nature gives also the tumor agent an opportunity to pass from one host to another of successive generations.

Thus middle aged mice that develop mammary carcinoma spontaneously can be found occasionally among the animals sold to clinical laboratories by dealers and known as market mice. Such animals are of course of unknown genetic origin being the offspring of promiscuous breeding. When such

tumor bearing females were mated successively to several genetically unrelated males numerous spontaneous mammary carcinomas developed among their offspring (24-25) apparently these mice transmitted the tumor agent to their progeny even though they were far from following any rules of pedigreed inbreeding.

In another experiment mice that were born to market albino mice of unknown ancestry were foster nursed by female mice of the C₃H line whose milk was known to contain the tumor agent as a result 14 of 17 foster nursed females i.e. 82 per cent developed mammary carcinomas upon reaching approximately 1 year of age (7). Eighteen sisters of these females were nursed as controls by their own albino mothers and none of these died of cancer. These experiments were repeated and confirmed in this laboratory (32). In our series 23 albino females of unknown ancestry obtained from a clinical laboratory were transferred within 24 hours after birth for the purpose of foster nursing to female mice of the C₃H line (Fig. 7). Sixteen of these i.e. 70 per cent developed carcinomas at the average age of 15 months (Fig. 8). No tumors were observed among the not fostered females. Thus, here again the ingestion of the tumor agent in infancy resulted in the development of tumors in mice of unknown ancestry.

HORMONAL STIMULATION AND BREAST CANCER

When the initial observations were made suggesting that mammary carcinoma could be produced in male mice by either implanting ovaries or injecting follicular hormones it was thought at first that this was a cancer of hormonal origin (39). Only subsequent experiments have demonstrated that no amount of follicular hormone would produce mammary carcinomas in mice that do not carry the specific tumor agent (18, 40, 47, 54). Thus in families of mice that apparently carry the tumor agent i.e. in which the majority of females develop spontaneous mammary carcinomas the male population remains free from these tumors even though the males also carry the tumor agent. Such males will develop mammary carcinomas however if their mammary glands are stimulated by early and po-

tent injections of follicular hormone. On the other hand similar application of the follicular hormone to male mice belonging to families free from the mammary carcinoma agent, i.e. to families whose females do not develop breast cancer will not result in the development of tumors. If males of such tumor free families, however are foster nursed by females carrying the tumor agent and then injected with follicular hormones mammary tumors will develop.

It is now clear that mammary carcinoma is not caused by hormonal stimulation, but by the transmissible tumor agent. Obviously the agent must act on susceptible hosts to produce symptoms of the disease in addition to the general inherited susceptibility of the host, the agent apparently also requires active, and adequately stimulated mammary gland tissue in order to actually form a tumor. Repeated pregnancies, or injection of potent follicular hormones may in such cases prompt the development of tumors (4, 11) provided of course that the specific tumor agent is harbored by the host.

The mammary carcinoma agent seems to have a discriminatory affinity for particular groups of cells (mammary glands) within the host. It is well to remember however that in this respect again the mammary carcinoma agent does not, in principle, differ from many other pathogenic viruses. To give an example the infantile paralysis virus has a distinct affinity to certain cells of the spinal cord of man. Many other micro-organisms possess a limited affinity to certain groups of cells within a limited range of susceptible hosts.

Hormonal stimuli may also distinctly influence the susceptibility of the host to various communicable diseases; thus, males have long been observed to be more susceptible than females to many infectious diseases in both human and animal pathology (18). On the other hand the hormonal stimuli may in certain instances increase the resistance of the host to parasitic agents. *Tinea tonsurans*, for example occurs in childhood but does not usually affect sexually mature individuals (45).

Thus, hormonal stimulation like inherited susceptibility may at first sight perhaps, ap-

Fig. 7 A newly born litter of albino 'market' mice of unknown ancestry, was foster nursed by a female of the C3H line whose milk contained the tumor agent

pear to be of unusual importance in the origin of mammary carcinoma of mice and that of cancer in general. Upon reviewing these observations on a broader basis however it becomes apparent that inherited susceptibility and hormonal stimulation are both also essential in the development of various communicable diseases.

THE IMPLICATIONS OF THE NEW APPROACH TO THE PROBLEM OF CANCER

The theoretical implications of the observations discussed are considerable. To begin with it appears difficult to consider that the mouse mammary carcinoma develops spontaneously. Breast cancer in mice appears to be no more spontaneous than a case of tuberculosis or typhoid fever. Provided that sufficient records are on hand each case of tuberculosis or typhoid fever could obviously be traced to another case of similar disease, the conditions being caused by specific transmissible agents. The same appears to be true for mammary carcinoma of mice. It is well to remember that only a generation or two ago many physicians thought that tuberculosis, typhoid fever, or for that matter a number of other communicable diseases were of spontaneous origin and resulted from various different internal and external causes. As late as 1885 typhoid fever and diphtheria were believed to originate *de novo* in filthy surroundings (44). The discussion on spontaneous tuberculous degeneration (43) printed

in the *Bulletin* of the French Academy of Medicine in 1867 may appear amusing to a contemporary physician in 1866 however the suggestion advanced by Villemin (55) that tuberculosis is not a spontaneous disease but is caused by a transmissible parasitic agent did not gain much support among his contemporary colleagues. It took years to demonstrate the law of obligate communicability for all infectious diseases.

We do not know at the present time of any communicable disease that would develop *de novo*. There is no convincing evidence to support the idea of spontaneous generation of any, no matter how small parasitic agents. Invisible viruses are much more difficult to detect than the larger microbes. If they are harbored by a host without causing symptoms of disease they may remain undetected without attracting attention of the most careful observer. They may then pass to other hosts and at a later date cause symptoms of disease so unexpectedly as to give the impression of being produced *de novo* or by some obscure process of mutation.

One of the most interesting features of the epidemiology of mouse mammary carcinoma is its vertical transmission, i.e. the passage of the virus from one generation to another. In the case of many common communicable diseases the chain of infection spreads among individuals of the same generation, i.e. horizontally, as a result many consecutive cases of transmission of the disease from one in

pear to be of unusual importance in the origin of mammary carcinoma of mice and that of cancer in general. Upon reviewing these observations on a broader basis however it becomes apparent that inherited susceptibility and hormonal stimulation are both also essential in the development of various communicable diseases.

THE IMPLICATIONS OF THE NEW APPROACH TO THE PROBLEM OF CANCER

The theoretical implications of the observations discussed are considerable. To begin with it appears difficult to consider that the mouse mammary carcinoma develops spontaneously. Breast cancer in mice appears to be no more spontaneous than a case of tuberculosis or typhoid fever. Provided that sufficient records are on hand each case of tuberculosis or typhoid fever could obviously be traced to another case of similar disease the conditions being caused by specific transmissible agents. The same appears to be true for mammary carcinoma of mice. It is well to remember that only a generation or two ago many physicians thought that tuberculosis, typhoid fever or for that matter a number of other communicable diseases were of spontaneous origin and resulted from various different internal and external causes. As late as 1885 typhoid fever and diphtheria were believed to originate *de novo* in filthy surroundings (44). The discussion on spontaneous tuberculous degeneration (43) printed

in the *Bulletin* of the French Academy of Medicine in 1867 may appear amusing to a contemporary physician in 1866 however the suggestion advanced by Villemin (55) that tuberculosis is not a spontaneous disease but is caused by a transmissible parasitic agent did not gain much support among his contemporary colleagues. It took years to demonstrate the law of obligate communicability for all infectious diseases.

We do not know at the present time of any communicable disease that would develop *de novo*. There is no convincing evidence to support the idea of spontaneous generation of any no matter how small parasitic agents. Invisible viruses are much more difficult to detect than the larger microbes. If they are harbored by a host without causing symptoms of disease they may remain undetected without attracting attention of the most careful observer. They may then pass to other hosts and at a later date cause symptoms of disease so unexpectedly as to give the impression of being produced *de novo* or by some obscure process of mutation.

One of the most interesting features of the epidemiology of mouse mammary carcinoma is its vertical transmission, i.e. the passage of the virus from one generation to another. In the case of many common communicable diseases the chain of infection spreads among individuals of the same generation, i.e. horizontally, as a result many consecutive cases of transmission of the disease from one in

Fig. 9 Cancer appears to be a spontaneous disease. In most instances information available is limited to three generations, that is to the individual concerned, and the next succeeding and preceding generations.

dividual to another occur within a comparatively short time and the whole picture of a communicable disease is clearly discernible to any individual observer. In the case of tumors however the epidemiological picture is fundamentally different. Thus in the case of mammary carcinoma at least the pathogenic agent is transmitted from one individual to another of successive generations many of the individual carriers may actually harbor and transmit the virus but never show any symptoms of disease.

Theoretically it is possible to assume that breast cancer could kill the great grand mother then skip the grandmother mother and so forth only to reappear perhaps in the great granddaughter in its usual form of a typical breast carcinoma. In reality the tumor agent does not skip any of the individuals through which it passes. They all carry the tumor agent though many of them never show any symptoms of tumors. Because however the mammary carcinoma agent can cause no symptoms, and because it is transmitted vertically it may actually submerge for one two or more generations of hosts

disappearing entirely from the sight of the most patient observer (Figs. 9 and 10). Years, and in man perhaps even a century or two may sometimes elapse between cases of disease that have been caused by transmission of the same pathogenic agents (34, 35).

SPONTANEOUS GENERATION" AND MOUSE MAMMARY CARCINOMA

The law of obligate communicability is at the present time so generally accepted that no one would venture to state that he observed a case of spontaneous tuberculosis not caused by bacillus tuberculosis even though here and there cases of unquestionable clinical tuberculosis might have been observed with apparent difficulty in demonstrating the presence of the specific pathogenic agent. In the case of mammary carcinoma of mice, however it appears to some authors at least perfectly plausible to state that a case of mouse mammary carcinoma has been observed which has not been caused by a transmissible milk factor (i.e. tumor virus) because no presence of such a tumor agent could be demonstrated in the particular case by the investigators (37). Thus, some investigators still believe that certain mouse mammary cancers are caused by a specific, transmissible agent while others, clinically identical tumors developed *de novo* (16) and are of spontaneous origin. Actually, however the concept of "spontaneity" of mouse mammary carcinoma seems untenable in view of the experimental evidence suggesting that breast cancer of mice is communicable from generation to generation and that its appearance can be effectively prevented by isolating the potentially cancerous mothers from their newly born progeny.

HUMAN TUMORS

The 'vertical transmission of mammary carcinoma in mice from one host to another through a filterable agent contained in the milk of nursing mothers has been established experimentally beyond any reasonable doubt. The question arises immediately whether this origin of breast cancer is limited to mice or is valid also for other species of mammals including man. In addition the question also arises whether tumors other than mammary

carcinoma have a fundamentally different etiology

No exact answer is possible at the present time to either of these important questions. Until more information on experimental cancer is obtained, only a tentative assumption based on theoretical considerations could be ventured. It is possible to assume however that mammary carcinoma of mice does not represent a form of cancer different from breast cancer in other mammals. If this assumption is correct, the law of obligate communicability may in the future be established also for breast cancer in such animals as rats, rabbits, or dogs and perhaps also in women.

PREVENTING HUMAN BREAST CANCER BY ARTIFICIAL FEEDING?

Should such a possibility materialize the eradication of human breast cancer may become feasible by the simple method of artificial feeding of infants born to mothers having a family history of tumors (17 33 34 35).

There is at the present time no other way of suspecting the presence of the tumor agent in the milk of a nursing female mouse except by checking her family record for the occurrence of tumors. A female mouse whose milk contains the tumor agent is in perfect health at the time of nursing; she will develop mammary carcinoma upon reaching middle age if she develops a tumor at all; she may die before she reaches the tumor age; on the other hand she may live her normal life span and yet never develop a tumor (although she carries and transmits the tumor agent) if her diet is restricted (36 53 58) so as to cut her caloric intake by 30 to 50 per cent. The only way to determine whether she carries and transmits the tumor agent is to check her family record. Her mother might have died without a tumor as well as her grandmother, but perhaps a sister of her mother or her great grandmother for instance developed a mammary carcinoma.

The same may be true for human breast cancer. Thus a history of breast cancer in the family of a nursing and apparently healthy mother may indicate the presence of a tumor agent in her milk. Since no more than a few hours of breast feeding may suffice to transfer

Fig. 10. The vertical transmission of cancer becomes discernible only when records are available covering a sufficient number of generations.

the tumor factor, the conclusion seems justified that breast feeding in such instances should be abandoned *from birth*. It might suffice to omit breast nursing for one single generation in order to interrupt the flow of the virus. Breast feeding could then be resumed in the succeeding generations.

Since the tumor agent does not appear to resist heating to 61 degrees C. for 30 minutes (7 8) feeding of pasteurized human milk (56) should also be considered.

THE ORIGIN OF TUMORS OTHER THAN MAMMARY CARCINOMA

The second important question requiring clarification is that dealing with the possible origin of tumors other than mammary carcinomas. Except for some particular tumors of dogs, chickens, frogs or rabbits there is in the great majority of instances no evidence to suggest that the various sarcomas and carcinomas that develop for obscure reasons in

different organs of animals and man, are caused by transmissible agents. And yet, it is difficult not to be impressed by the fact, that in various species of hosts, such as mice, rats, rabbits, chickens, fish, cattle etc. families have been observed with an incidence of either tumors, or allied diseases, such as leucemia, substantially higher than that of the average population. Also in man it is rather difficult to ignore the often striking frequency of malignant tumors developing in members of families of patients suffering from cancer (33). This observation has been made so often that a positive for cancer family record is actually considered to be of diagnostic value (22).

In principle it appears possible, perhaps even reasonable, to assume, that mammary carcinoma of mice does not represent a form of cancer fundamentally different from at least some of the other malignant neoplasms. If this assumption is correct, the law of obligate communicability may in the future become established also for tumors other than breast cancer (33). Such an assumption would not necessarily imply that milk only should be considered as means of natural transmission of a causative tumor agent. Tumors are not limited to mammals, and it would only be logical to assume that means of transmission other than milk also exist should such transmission occur at all.

A WORKING HYPOTHESIS

The observations discussed above are as yet insufficient to draw any generalized conclusions. It is possible nevertheless, to advance a working hypothesis as to the origin of at least certain malignant neoplasms in animals and also in man.

There may exist a group of transmissible agents causing tumors in animals and in man these agents would be so small as to be invisible under an ordinary optical microscope they would possess many of the characteristics of pathogenic viruses. These agents would be fundamentally similar in certain features of their behavior. Thus, they would attack certain groups of cells within certain hosts live and multiply in such cells as a rule these tumor agents would be frugal and moderate in their requirements, and would not apparently

injure the host. For obscure reasons, however the pathogenicity of the agent may sometimes change during the latter part of the life of the host, and a tumor would then develop usually sealing the fate of the host, i.e. growing progressively and if not treated killing the host. The survival of the agent would have been in the meantime secured however by transmission to another host occurring as a rule prior to the appearance of symptoms of a tumor in the transmitting individual.

One of the most striking features of the pattern of natural transmission of these agents would be their faculty to pass 'vertically' from one host to another of successive generations. The generation-to-generation transmission with occasional 'skipping' of intermediate carriers, i.e. with skipping of generations, would make the task of tracing the epidemiological course of the tumor agent extremely difficult, and time consuming. Although the tumors would in principle belong to the general group of communicable disease, transmission would occur as a rule among hosts of successive generations.

The agent would appear to be able to attack new hosts efficiently in either their embryonic stage or in their infancy. A long asymptomatic phase of the disease would then follow during which the host would transmit the agent to the succeeding generation. The activation of the hitherto latent agent in the transmitting host would then follow though it would not always have to occur. The activation of the tumor agent could be prompted by a number of either general or local, non-specific, factors such as those related to aging, by hormonal stimuli or metabolic disturbances, by exposure to irradiation, or to certain systemic poisons, etc. In some instances, the activation of the agent could be prevented by either hormonal influences, by a restricted food intake, or perhaps by some other as yet obscure factors.

Although fundamentally similar in certain features of their behavior these tumor agents would be individually distinct, causing different malignant neoplasms, not unlike the array of rickettsial micro-organisms responsible for the various forms of typhus. If this assumption is correct, the number of animals,

and people, with demonstrable tumors would represent only a fraction of those actually carrying the disease (33)

SUMMARY AND CONCLUSIONS

1 Mammary carcinoma of mice, a disease essentially similar to breast cancer of women, is caused by a filterable agent, which is transmitted from one generation to another through the milk of nursing females. This agent can be destroyed by heating to 61 degrees C for 30 minutes i.e. it would not resist pasteurization. The agent has antigenic properties, and can be neutralized *in vitro* by a specific immune serum.

2 The development of mammary carcinoma in mice can be prevented by the simple method of isolating the newly born animals from their potentially cancerous mothers, and by transferring them for the purpose of nursing to female mice whose milk is free from the tumor agent.

3 Mice of either pedigreed inbred lines or offspring of promiscuous breeding can be infected in infancy by ingesting the mammary carcinoma agent. They remain then in perfect health, through their early adult life. Upon reaching one to one and a half years of age, however they develop mammary carcinomas. In the meantime they have transferred the tumor agent to their own offspring and have thus assured the continuation of the disease in the next group of hosts.

4. Thus a female mouse which is nursing is in perfect health at the time she is actually infecting her offspring with the tumor agent. The only indication suggesting that she harbors and discharges the tumor virus is her record showing that mammary carcinomas developed in her female ancestors.

5 These observations suggest that mammary carcinoma is not a spontaneous disease. The law of obligate communicability long established for other infectious diseases appears to be valid also for breast cancer of mice.

6 The natural transmission of mammary carcinoma agent occurs only from one host to another of successive generations. The term "vertical epidemic" has been suggested for this type of transmission of pathogenic agents

Many parasites of plants and insects follow this pattern of transmission, passing from one host to another through either seeds or ova. "Vertical epidemic, however, should not be confused with inheritance, these are two fundamentally different phenomena.

7 The possibility is discussed that mammary cancer of other mammals, including man may also be caused by agents similar to that responsible for mouse mammary carcinoma. If this assumption is correct, women who have a family history of tumors should not nurse their babies artificial feeding, or feeding with pasteurized human milk should be substituted. This simple preventive measure may interrupt the flow of the virus and eradicate human breast cancer within one generation. Breast nursing could then be resumed.

8 It is possible to assume that mammary carcinoma of mice is not exceptional in its etiology, but represents a condition essentially similar to other neoplasms. If this is true other malignant tumors may eventually prove to be caused by transmissible agents. It would then be logical to assume however, that milk is not the only means of transmission of such agents transfer through ova, and otherwise, would also have to be considered.

9 The hypothesis is advanced that there exists a group of viruses causing various malignant tumors in animals and in man. These viruses would live in close association with normal cells be usually frugal and moderate in their requirements, and cause no symptoms of disease. They would be transmitted among hosts of successive generations i.e. vertically. In most instances the carriers would never show any symptoms of tumors. Occasionally, however prompted by obscure factors, the tumor virus would become activated, causing a local new growth.

10 Because of the existence of many asymptomatic carriers however and the occasional "skipping" of generations it would only become possible actually to trace the host to-host passage of the "vertically" transmitted tumor agents when accurate and complete mortality records are on hand covering the span of many successive generations.

11 If this hypothesis is correct it would logically follow that should such records ever

become available, each case of human cancer could then be traced to another case of a malignant tumor in one of the patient's ancestors.

12. The comparatively high incidence of tumors in families of patients suffering from cancer long recognized by various observers, would thus assume a more than incidental significance. Accordingly a family history of cancer should perhaps be more appreciated from the point of view of its possible diagnostic value particularly in patients with symptoms difficult to be properly classified.

SUBMUCOUS LIPOMA OF THE COLON

CHARLES W MAYO M.D., F.A.C.S., and DONALD F GRIESS M.D., Rochester Minnesota

MANY reviews and individual reports of cases of submucous lipoma of the colon have appeared in the literature since Bauer in 1757, reported the spontaneous elimination of a lipoma, probably from the colon. A recent contribution to the subject is that of Pack and Booher, who stated that 153 cases of submucous lipoma of the colon had been reported in the literature to the time of completion of their paper.

The purpose of this study is to add to this number 19 cases of submucous lipoma of the large intestine in which operation has been performed at the Mayo Clinic from January 1, 1936 through December, 1947 and also to review briefly the salient features of symptomatology, situation and surgical procedures performed for the condition.

Comfort and Pemberton and McCormack reported 24 cases of submucous lipoma of the large intestine from the clinic. These together with the 19 cases reported in this paper make a total of 43 cases in which operation has been performed for this particular condition at the Mayo Clinic up to and through the year 1947.

Lipomas of the colon occasionally are found on routine necropsies; these growths are relatively small and asymptomatic and since they are incidental findings they are only of academic importance.

REPORT OF CASES

CASE 1. An unmarried woman aged 50 years came to the Mayo Clinic on October 31, 1935 because of attacks of pain in the right side. The attacks had occurred intermittently for 12 years; the last one a week before admission. Examination disclosed a fibroid tumor and retroversion of the uterus. Total hysterectomy, bilateral salpingo-oophorectomy and appendectomy were performed on November 2, 1935. Convalescence was uneventful and the patient was dismissed on November 25, 1935.

On February 10, 1936 she returned because of pain in the epigastric region which she had experienced first shortly after the previous operation and

which had increased steadily in severity. She also had had several attacks of mild intestinal obstruction. Physical examination revealed extreme tenderness and definite muscular rigidity in the right portion of the epigastrium. Roentgenologic examination of the colon revealed cecocolic intussusception, the cause of which could not be determined at the time.

On March 14 an exploratory laparotomy disclosed a lipoma of the cecum which had caused intussusception and partial obstruction of the intestine. Because the peritoneum in the ileocecal region was thickened and it was thought that the lesion might be malignant, about 3 inches (7.6 cm.) of the ileum, the cecum, the ascending colon and several inches of the transverse colon were excised and the continuity of the intestine was re-established by side-to-side anastomosis. An ileac stoma was established but this was closed at a later date. The pathologist reported that the tumor was a submucous lipoma which measured 6 by 5 by 4 centimeters. The surface of the tumor was ulcerated. When the patient was last heard from she was in good health.

CASE 2. A married woman aged 58 years came to the clinic on October 18, 1937. In February 1937 she first had noticed a mild burning pain in the right upper quadrant of the abdomen which had not been related to the ingestion of food. In August, 1937 roentgenologic examination had disclosed a filling defect in the first part of the transverse colon and in October 1937 roentgenologic examination had disclosed a polypoid tumor in the first part of the transverse colon. She had not had any diarrhea, constipation or change in bowel habit. Her stools had not contained any mucus or blood.

Physical examination revealed some tenderness in the right side of the abdomen. Proctoscopic examination did not reveal any abnormality. Roentgenologic examination of the colon revealed some changes in the cecum and ascending colon which were suggestive of amebic colitis. Therefore treatment for amebiasis was instituted. Roentgenologic examination a week later revealed a local inflammatory lesion in the cecum. Hospitalization and treatment were advised. A subsequent roentgenogram revealed a polypoid lesion which was thought to be a lipoma situated in the transverse colon near the hepatic flexure.

At laparotomy on November 12, 1937 the last 6 inches (15.2 cm.) of the ileum, the ascending colon and the transverse colon were found to be slightly thickened. This thickening was thought to be due to amebic colitis. A tumor was found in the hepatic flexure of the colon and it was removed through a transverse incision in the colon. The pathologist reported that the tumor was a submucous lipoma. It

measured 2 by 3 by 0.5 centimeters. The patient had an uneventful recovery. In a letter received from her 4 years later she did not complain of any difficulty.

CASE 3. A married woman, aged 43 years, came to the clinic on April 3, 1939, because of gall bladder colic. Her appendix and a cyst of the right ovary had been removed in 1916. A roentgenologic diagnosis of gallstones had been made in 1938. Hemorrhoids, with occasional bleeding and pruritus, had been present for many years. Proctoscopic examination had not been made.

Physical examination revealed an elongated mass, apparently of the colon, in the right lower quadrant of the abdomen. Roentgenologic examination disclosed that the gall bladder was not functioning in a normal manner. Roentgenologic examination of the large intestine was not made.

On April 6, 1939, exploratory laparotomy revealed a pedunculated tumor which projected into the lumen of the ascending colon. Because there was considerable inflammation of the surrounding tissues and since it was felt that the lesion might be malignant, about 4 inches (10 cm.) of the terminal portion of the ileum, the cecum, the ascending colon, and about half of the transverse colon were excised. The continuity of the intestine was re-established by side-to-side anastomosis. An enterostomy tube was inserted in the ileum at a point about 5 inches (12.7 cm.) above the line of anastomosis. The gall bladder also was removed. The pathologist reported that the tumor was a pedunculated lipoma of the cecum about 5 centimeters in diameter. The overlying mucosa was covered by an ulcer which was about 4 centimeters in diameter. The muscular coat of the surrounding intestine had undergone hypertrophy. The patient made an uneventful recovery.

CASE 4. A man, aged 5 years, came to the clinic on August 26, 1940, because of arthritis and the presence of blood in the stools. The small joints were swollen and tenderness was present over most of the joints. Examination of the abdomen did not disclose any abnormality. Proctoscopic examination disclosed external and internal hemorrhoids, grade 1 (on the basis of 1 to 4). Roentgenologic examination of the colon revealed diverticulosis and a polypoid tumor in the midportion of the descending colon.

At laparotomy on September 5, 1940, the descending colon and the first portion of the sigmoid flexure were found to be bound down rather tightly to the posterior portion of the abdominal wall because there was practically no mesentery. A soft nodule could be palpated in the descending colon. The colon was opened and the tumor was removed by dissection. The pathologist reported that the tumor was a submucous lipoma of the descending colon, 2.5 centimeters in diameter. The operative wound became infected but the patient recovered in a month.

CASE 5. A man, aged 50 years, came to the clinic on September 6, 1940, and stated that for the past 15 years he had had attacks of generalized, shifting,

transient abdominal pain that had not been associated with nausea or vomiting and had not given evidence of any symptoms referable to the intestinal tract. The attacks had occurred once or twice a year and had lasted from 1 to 3 days. He had found that a bland type of diet would prevent the attacks. The patient also complained of pain in the epigastrium and in the left upper quadrant of the abdomen which was relieved by alkalies and milk.

Physical examination did not reveal any abnormality. Proctoscopic examination disclosed internal and external hemorrhoids. Roentgenologic examination of the stomach did not disclose any abnormality. A similar examination of the gall bladder revealed that this organ contained a calculus but that it was functioning normally. Roentgenologic examination of the colon disclosed a nonseminole polypoid tumor which was believed to be situated in the descending colon near its junction with the sigmoid flexure. The roentgenologist expressed the opinion that the tumor might be a lipoma.

Exploratory operation was performed on September 14, 1940. The tumor was found to be situated at the junction of the descending colon and sigmoid flexure. It was removed through a transverse incision in the colon. The pathologist reported that the tumor was a submucous lipoma of the sigmoid flexure, 3 centimeters in diameter.

The patient was in good condition when he was discharged on October 7, 1940. In a letter dated November 22, 1940, he stated that he was in good health.

CASE 6. A man, aged 43 years, came to this clinic on September 5, 1941. About a year previously he had begun to have attacks of cramping pain in the right upper quadrant of the abdomen. These attacks had occurred about once a week, had lasted from 1 to 3 minutes, and then had terminated suddenly. Although they had occurred at almost any time, they had had a tendency to start after meals. Four months before the patient came to the clinic, the frequency of the attacks had increased so that they had been present every day and had lasted about an hour during which the pain occurred at intervals of 2 to 4 minutes. The pain sometimes had awakened the patient at night and it sometimes had been present every half hour during the day. It was relieved by a bowel movement or by the passage of flatus. It usually was localized in the right upper quadrant of the abdomen but it sometimes extended to the left scrotal region. There had not been any diarrhea and the patient never had seen any blood in the stools.

Physical examination revealed a tender, movable mass in the right upper quadrant of the abdomen. Roentgenologic examination disclosed ileocolic intussusception. The intussusception first was observed in the middle of the transverse colon but in the course of the examination it was reduced as far as the hepatic flexure. At the completion of this part of the examination, the intussusception involved only the ileum and cecum. The roentgenologist reported

that there probably was a tumor or Meckel's diverticulum in the distal portion of the ileum.

On September 10, 1941, an exploratory laparotomy revealed intussusception of the cecum and ascending colon into the transverse colon. A tumor appeared to be attached to the first portion of the ascending colon by a thick pedicle. Because of the redundancy caused by repeated intussusception, about 4 inches (10 cm.) of the terminal portion of the ileum, the cecum and the ascending colon were excised. The continuity of the intestine was re-established by end-to-end anastomosis. The pathologist reported that the tumor was an ulcerating submucous lipoma of the cecum. It measured 6.5 by 5 by 5 centimeters and was situated opposite the ileocecal valve. In June, 1943, the patient reported that he was in good health.

CASE 7. A married woman, aged 48 years, registered on February 2, 1942, because of recurring attacks of colicky cramp which had been present for 4 months. The pain was situated in the right half of the abdomen and extended to the lower part of the right side of the thorax. It was not related to the ingestion of food or fluids but occurred in regular rhythm and kept her up at night; it lasted from 2 to 5 minutes and then disappeared for several minutes. It was relieved by bowel movements. In the past 4 months the number of bowel movements had increased from one to two a day and the stools were softer than they had been previously. The patient was nauseated and belched frequently. There was no blood in the stools.

Physical examination disclosed tenderness in the right upper quadrant of the abdomen. Proctoscopic examination disclosed small external and internal hemorrhoids. Roentgenologic examination of the colon disclosed a polypoid tumor about 5 centimeters in diameter which appeared to be attached to the lateral wall of the first part of the ascending colon by a pedicle. When the roentgenologic examination of the colon was started the ascending colon was found to be invaginated into the transverse colon as far as the midportion of this segment.

Laparotomy was performed on February 7, 1943. A tumor about the size of a hen's egg was found in the ascending colon. Although the tumor appeared to be benign it had caused the terminal portion of the ileum, the cecum and the ascending colon to become invaginated into the transverse colon as far as the midportion of this segment. The last 3.5 inches (8.9 cm.) of the ileum, the cecum and the ascending colon were excised and the continuity of the intestine was re-established by end-to-end anastomosis. The operation was completed in a single stage. The pathologist reported that the tumor was a submucous lipoma of ascending colon which measured 5 by 5 by 4 centimeters. An ulcer, 3.5 centimeters in diameter, was found on the overlying mucosa. The patient made an uneventful recovery.

CASE 8. A man, aged 53 years, came to the clinic on January 25, 1943, because of abdominal cramps and diarrhea which had been present for 3 weeks. He

also had discovered a painful mass in the left lower part of the abdomen. He had lost 10 pounds (4.5 kgm.) in the previous 6 months and had had occasional attacks of gaseous distention which had been relieved by the passage of flatus. Two weeks before admission he had had an attack of diarrhea and had noticed blood in the stools.

Physical examination revealed a fixed, slightly tender mass in the sigmoid flexure just above the brim of the pelvis. This mass was about 12 centimeters long. Proctoscopic examination revealed hemorrhoids. Roentgenologic examination disclosed a polypoid lesion of the descending colon at the level of the crest of the ilium. It was felt that the lesion probably was a carcinoma.

On January 29, 1943, exploratory laparotomy revealed a lesion in the descending colon just below the splenic flexure. The involved segment of the colon was thickened and congested; its appearance suggested intussusception or intestinal obstruction. The colon was exteriorized over a three-bladed clamp and about half of the transverse colon and most of the descending colon were excised. The pathologist reported that the tumor was a submucous lipoma of the descending colon which measured 4 by 3 by 2 centimeters and had caused intussusception into the sigmoid flexure. An ulcer which measured 3 by 2 centimeters was present on the surface of the tumor. The colonic stoma was closed on March 9, 1943.

The patient returned to the clinic for examination of his right knee on June 11, 1946, and at that time he did not have any symptoms referable to the intestinal tract.

CASE 9. A married woman, aged 46 years, came to the clinic on April 7, 1943. She had undergone appendectomy in 1919. Three years before admission pain had developed in the epigastrium and had extended to the right lower quadrant of the abdomen. It had been aggravated by jolting and had been rather constant until a regimen for cholecystic disease had caused it to disappear. However, 3 months before she came to the clinic she again experienced epigastric pain which extended to the entire right side of the abdomen; it was a dull type of pain which usually occurred before meals but sometimes lasted for 24 hours. She complained of gaseous distention of the stomach which was aggravated by the ingestion of fried foods and was relieved by belching. She passed considerable flatus with her bowel movements. She did not give any history of pain in the right shoulder or of jaundice, acholic stools, nausea or vomiting.

Physical examination revealed epigastric tenderness and an elongated mass in the right upper and lower quadrants of the abdomen. Mass extended upward to a point just above the umbilicus; it was tender, moved with respiration and had the consistency of rubber. Roentgenologic examination of the colon revealed a polypoid lesion of the cecum which was about 5 centimeters in diameter. Intussusception was found in the region of the hepatic flexure of the colon but the invagination was reduced easily.

by manipulation while the opaque enema was being administered. Roentgenologic examination of the stomach and gall bladder did not disclose any abnormality of these organs.

April 13, 1943, exploratory laparotomy revealed a tumor which appeared to be situated in the ascending colon near the cecum and which had caused intussusception. The terminal portion of the ileum, the cecum and the remainder of the right half of the colon were excised and the continuity of the intestine was re-established by side-to-side anastomosis. The pathologist reported that the tumor was a submucous lipoma of the cecum. It was about 5 centimeters in diameter and the overlying mucosa was ulcerated. Situated near the tumor were several pseudopolyps which varied in size from 5 millimeters to 1 centimeter in diameter. The patient's convalescence was uneventful.

CASE 10. A married woman, aged 41 years, came to the clinic on June 6, 1943. She had undergone appendectomy in 1918. In October, 1942, she first had noticed burning pain in the epigastrium 1 hour after meals. It had been relieved by vomiting and by the taking of bicarbonate of soda. Although roentgenologic examination had not disclosed any evidence of peptic ulcer, an ulcer regimen had been instituted. In November, 1942, the patient had had an attack of diarrhea which had lasted 1 month and during which time she had passed from 8 to 10 bloody stools during the day and from 3 to 4 during the night. A similar attack had occurred in February, 1943, but had disappeared in about 3 weeks, although the diarrhea had recurred about 2 weeks later and had persisted until the patient came to the clinic. Cramps in the lower part of the abdomen had accompanied each bowel movement. When diarrhea had not been present, the patient's bowels had moved only with the aid of a cathartic and the stools had been the size of a pencil.

On examination the abdomen was slightly distended and the left lower quadrant was tender. Palpation also disclosed a small mass in this quadrant. Proctoscopic examination disclosed hemorrhoids and a small rectal polyp; the polyp was fulgurated. Roentgenograms of the stomach and gall bladder showed normal conditions. Roentgenologic examination of the transverse colon disclosed a large polypoid tumor in this portion of the colon situated near the hepatic flexure. The roentgenologist expressed the opinion that there might possibly be several other smaller polypoid tumors, both proximal and distal to the large tumor. The smaller polyps could not be demonstrated satisfactorily by roentgenoscopy because of the presence of intussusception which could not be reduced during the examination.

On June 11, 1943, excision of the terminal portion of the ileum, the cecum and the right half of the colon was performed. The continuity of the intestine was re-established by side-to-side anastomosis. The pathologist reported that the tumor was a pedunculated submucous lipoma which measured 8 centimeters in diameter. An ulcer 5 centimeters in

diameter was present on the surface of the tumor. The patient was in good health when she was dismissed on June 30, 1946.

CASE 11. A man, aged 53 years, registered on June 19, 1943, because of diarrhea of 2 weeks' duration and of red blood in the stools 7 days before admission. His appendix had been removed in 1917. During the year before he came to the clinic he had been receiving prostatic massage for aching pain in both groins. The massage was continued although the pain had subsided in the past 6 months. Since December, 1942, he had had frequent attacks of mild abdominal cramps which always had been relieved by a bowel movement, the stools having been formed and no blood having been noted. Diarrhea, with 4 to 6 bowel movements daily, had developed 2 weeks prior to admission and medical treatment for the condition had been followed by obstipation. Seven days before registration there had been marked rectal bleeding which had persisted for 36 hours. Two days later, roentgenologic examination had disclosed a lesion of the sigmoid. Three days before he came under our care, severe abdominal cramps developed which were relieved by the onset again of diarrhea.

On physical examination, deep tenderness was noted in the left groin. Proctoscopic examination of the distal 24 centimeters of the intestine revealed that the upper limit of this portion of the intestine was moderately fixed to surrounding structures and that it was angulated anteriorly. Internal hemorrhoids, grade 1-4, were present. Roentgenologic examination disclosed a polypoid tumor at the junction of the descending colon and the sigmoid flexure which had a tendency to cause intussusception. The retrograde flow of barium was partially obstructed.

Laparotomy was performed on June 26, 1943, at which time the polypoid tumor was found in the upper part of the sigmoid flexure. Because it was felt that the tumor might be malignant, about 10 inches (25.4 cm.) of the sigmoid flexure was excised. The continuity of the intestine was re-established by end-to-end anastomosis over a three-bladed clamp. The pathologist reported that the tumor was a pedunculated submucous lipoma of the sigmoid flexure, 4 centimeters in diameter. An ulcer 3 centimeters in diameter was found on the surface of the tumor. Ten days after the operation the patient passed a small renal calculus.

On September 16, 1944, the patient returned to the clinic for re-examination. At that time roentgenologic examination of the colon and terminal portion of the ileum did not disclose any abnormality.

CASE 12. A married woman, aged 61 years, came to the clinic on September 22, 1943, because of a painful swelling of the right knee. She was troubled with constipation but she occasionally passed 2 or 3 loose stools daily. She also complained of gaseous distention of the stomach and of belching. Physical examination disclosed tenderness over the cecum and a questionable mass in this region. Roentgenologic examination revealed a polypoid tumor in the right portion of the colon.

Exploratory laparotomy was performed on October 5 1943. A tumor was found in the ascending colon just above the cecum. The tumor which was situated between the muscular and mucosal layers of the colon was removed by dissection. The pathologist reported that the tumor was a submucous lipoma. It measured 8 by 5 by 2 centimeters. The patient made an uneventful recovery and was dismissed from our care on October 29 1943.

The patient returned in January 1946 because of intermittent aching and swelling in the right side of the abdomen. Physical examination did not disclose any abnormality and roentgenograms of the stomach and colon showed normal findings.

CASE 13. A married woman aged 58 years came to the clinic on October 26 1944 because of constipation which had been present for 4 years and which had increased in severity. She said that the constipation could be relieved with enemas. On several occasions the bowel movements had been preceded by the passage of a small amount of mucus and 5 months before admission a small amount of blood had been passed in the stool.

Physical examination revealed an adenoma of the right lobe of the thyroid gland and a palpable mass in the left side of the epigastrium. Roentgenologic examination disclosed a polypoid tumor in the mid portion of the descending colon which had caused intussusception.

On November 8 1944 the involved portion of the descending colon was excised and the continuity of the intestine was re-established by end to-end anastomosis. The pathologist reported that the tumor was a submucous lipoma which measured 5 centimeters in diameter. An ulcer 4 centimeters in diameter was present on the mucosal surface of the tumor.

CASE 14. A married woman aged 50 years registered on November 2 1944. Six weeks previously she had felt a tumor in the middle of the abdomen. Roentgenologic examination of the kidneys and gall bladder had failed to disclose any abnormality. The tumor had disappeared after castor oil had been administered in the preparation of the patient for roentgenologic examination of the colon. She subsequently had felt the tumor on 3 or 4 occasions but it had disappeared after she had taken an enema or a dose of castor oil. She had indigestion and said that she was passing an increased amount of flatus. She always had been constipated.

Physical examination revealed a lipoma the size of an egg on the posterior wall of the thorax. Roentgenologic examination of the colon disclosed a polypoid tumor about 5 centimeters in diameter. The tumor appeared to be situated in the descending colon and at times had caused the ascending colon to become invaginated into the transverse colon. Proctoscopic examination did not reveal any abnormality.

On November 14 1944 excision of the cecum and several centimeters of the ileum was performed and the continuity of the intestine was re-established by side to-side anastomosis. The pathologist reported

Fig. 1. Case 16. Pedunculated submucous lipoma.

that the tumor was a pedunculated submucous lipoma 4 centimeters in diameter which was situated at the juncture of the cecum and the ascending colon. An inflamed ulcer 1 by 1 by 5 centimeters was present on the surface of the tumor.

The patient was in good health when she returned to the clinic for examination on October 12 1945.

CASE 15. A man aged 62 years registered on September 18 1946. Tonsillectomy had been performed in 1928 and a rectal fistula had been excised in 1932. Constipation had been present intermittently for a year and had been associated with pain in the left lower quadrant of the abdomen and with the passage of bright red blood in the stools. However for one period of 3 months he had not passed any blood. He had not had any diarrhea or obstipation nor had he lost any weight.

Physical examination did not reveal any abnormality. Proctoscopic examination disclosed hemorrhoids grade 1. Roentgenologic examination disclosed a large polypoid tumor in the descending colon just above the level of the crest of the ilium. Since the tumor was radiolucent the roentgenologist expressed the opinion that it might be a lipoma.

Laparotomy was performed on October 18 1946. A tumor was found in the wall of the descending colon just above the level of the anterior superior spine of the ilium. By means of an incision in the serous and muscular coats of the colon it was possible to remove the tumor without opening the lumen of the intestine. The pathologist reported that the tumor was a submucous lipoma of the descending colon which measured 5 by 3 by 2 centimeters. The postoperative convalescence was uneventful.

CASE 16. A man aged 55 years came to the clinic on June 27 1944 because of hemorrhoids. Proc-

Fig. Case 9. Lipoma with laceration of overlying mucous membrane.

oscopic examination revealed, in addition to the hemorrhoids, 3 small polyps in the lower 10 centimeters of the rectum. These tumors were fulgurated. Roentgenologic examination disclosed a sessile polypoid tumor in the ascending colon about 2.5 centimeters in diameter. Removal of the tumor was advised but the patient returned to his home.

He returned to the clinic on October 7, 1946, and at that time he did not have any symptoms that were referable to the gastrointestinal tract. Examination of the abdomen did not reveal any abnormality. Proctoscopic examination disclosed tiny polyps in the last 3 centimeters of the rectum. These tumors were fulgurated. Roentgenologic examination again revealed the polypoid tumor in the ascending colon which appeared at that time to be slightly larger than it had at the time of the patient's previous examination here.

Laparotomy was performed on November 21, 1946. The patient was rather obese and because of the presence of a large amount of fat and many epiploic tags, it was not possible to determine whether or not a polyp was present in the colon. A transverse incision was made in the hepatic flexure and two Deaver retractors were inserted. A yellow polypoid tumor then popped out of the incision. It was freely movable beneath the mucous membrane. It was squeezed from its attachment; the stalk was transfixed and ligated with a double cotton suture and the tumor was excised. The pathologist reported it to be a pedunculated submucous lipoma which measured 4 by 5 by 2 centimeters and weighed 23 grams (Fig. 1).

In letter dated December 28, 1946, the patient stated that he was in good health.

CASE 17. A married woman, aged 40 years, came to the clinic in January, 1947, complaining of spells of extreme weakness and heaviness which were thought to be functional and on a menopausal basis. She complained of gas at the time of these attacks but did not have nausea or vomiting. Some blood had been noted occasionally in the stools.

On examination the patient was found to have moderate hypertension; the blood pressure ranged between 150 and 170 millimeters of mercury systolic and more than 90 diastolic. On proctoscopic examination a small polyp was found 8 centimeters from the dentate margin and this was fulgurated. Roentgenographic examinations of the stomach and gall bladder revealed nothing significant but a spot film roentgenogram of the colon revealed a sessile polypoid lesion about 2 centimeters in diameter in the cecum just below the ileocecal valve. The growth was not visible in the ordinary roentgenogram.

At operation in February, 1947, appendectomy and transcolonoscopic removal of a lipoma 2.5 centimeters in diameter of the cecum were performed. No other abnormality was found except some fibroids of the uterus.

The convalescence was without incident and the patient was dismissed from our care on the twelfth postoperative day.

CASE 8. A woman, aged 66 years, came to the clinic in March, 1947, complaining of "gnaug epigastric distress" which had been present for a period of 8 to 10 years. Her gall bladder and appendix had been removed in 1928. She had had chronic constipation for which she habitually had used cathartics and enemas; there had not been any blood in the stools. She had not had nausea or vomiting. Her weight and general physical appearance were normal and physical examination gave essentially negative results except for mild tenderness over the upper part of the abdomen. Roentgenographic examination revealed a large diverticulum of the duodenum and some diverticula of the colon but did not disclose any other abnormality in the colon or terminal portion of the ileum.

Surgical treatment was advised for the duodenal diverticulum and, accordingly, on March 17, 1947, resection was performed for the duodenal diverticulum. Further exploration of the abdomen revealed what appeared to be enteritis of the terminal portion of the ileum and a palpable mass in the cecum. Right hemicolectomy was performed with removal of the distal 14 feet (76 cm.) of ileum, the cecum, ascending colon and hepatic flexure. An end-to-end ileo-transverse colostomy was done.

Examination of the removed tissue disclosed multiple nonspecific inflammatory ulcers, in various stages of healing, in the terminal 25 centimeters of the ileum; peri-ileitis had caused angulation of the ileum above the ileocecal valve and had produced mechanical obstruction. Diverticula were found in the colon and a submucous lipoma 5 centimeters in diameter was present in the ileocecal valve.

Intermittent episodes of the intussusception might be an explanation of some of the patient's symptoms.

CASE 10. A married woman, aged 52 years, came to the clinic in December, 1947, complaining of discomfort in the left lower quadrant of the abdomen of more than 2 years' duration. She had been very ill 2 weeks before admission with intermittent cramps

in the left lower abdominal quadrant nausea and vomiting. Bright red blood had been passed in the stool. A mass had been discovered and she had had signs and symptoms of obstruction. She had been hospitalized and a presumptive diagnosis of carcinoma of the colon had been made. Under care the attacks had lessened in severity and she decided to come to the Mayo Clinic for treatment. The patient stated that she had lost 20 pounds (9.1 kgm) in the past year and that she was having a constant dull ache with intermittent crampy pains. A smooth tender mass was found in the left side of the abdomen. On rectal examination red blood was noted but there was no mass. Proctoscopic examination for a distance of 26 centimeters also yielded normal findings. A roentgenographic examination revealed an obstructing lesion in the upper portion of the descending colon; it was not possible to force the barium above the lesion, the exact nature of which was indeterminate. Obstruction of the bowel above this level was apparent; there was a large amount of feces in the ascending colon and transverse colon and a loop of small intestine was distended with gas. The lesion did not appear to have undergone malignant change.

Operation was performed on December 20, 1947, at which time an intussuscepting lesion was found in the descending colon. The intussusception was reduced and an incision was made in the colon near the base of the palpable polypoid growth. A lipoma which measured 7.5 by 5.5 by 5 centimeters with ulceration of the overlying mucous membrane (Figs. 2 and 3) was removed and the colonic incision was closed.

The patient's convalescence was uneventful and she was dismissed from the hospital on the tenth postoperative day.

COMMENT

In the 19 cases which we have reported the lipomas were distributed rather evenly in the different segments of the large intestine. The site of involvement was as follows: cecum in 6 cases, ascending colon in 4 cases, hepatic flexure in 1 case, transverse colon in 1 case, descending colon in 5 cases, and the sigmoid flexure in 2 cases.

The differential diagnosis of lipoma of the large intestine and carcinoma of the large intestine is rather difficult. In the 19 cases reported herein the youngest patient was 41 years old and the oldest patient was 66 years old. The average age of the 19 patients was 52 years, which closely approximates the age at which carcinoma of the colon is most likely to occur. Twelve of the 19 patients were women and 7 were men.

Although the symptoms of submucous lipoma closely resemble those of carcinoma, cer-

Fig. 3. Case 19. Same as Figure 2. Lipoma opened.

tain rather subtle differences become evident when a group of cases of submucous lipoma are compared with a group of cases of carcinoma. It should be emphasized, however, that these differences are of doubtful value in trying to distinguish these two lesions in an individual case. The symptoms of submucous lipoma may be of much longer duration than those of carcinoma. In the 19 cases which we have reported the longest duration of symptoms was 15 years and the shortest was 2 weeks. One patient did not have any symptoms that were referable to the gastrointestinal tract. Bleeding may or may not be a sign of lipoma of the colon. In 9 of these 19 cases blood in the stools had been noted. Anemia was by no means a prominent finding, certainly not comparable to the extent that it is found in the presence of malignant lesions.

Pain usually intermittent and often of cramping type was present in 12 of the 19 cases, most probably the result of intussusception. Intussusception tends to occur when the lipoma exists in a mobile portion of the colon and for this reason intussusception occurs more commonly, although not exclusively, when the lipomas are located in the right portion of the large bowel.

If one considers the cecum, ascending colon, hepatic flexure and the first portion of the transverse colon as the right portion of the colon, in 12 of the 19 cases the lipoma was situated in this segment and in 8 of these 12 cases a one stage resection was performed. In

Fig. 2. Case 9. Lipoma with laceration of overlying mucous membrane.

oscopic examination revealed, in addition to the hemorrhoids 3 small polyps in the lower 10 centimeters of the rectum. These tumors were fulgurated. Roentgenologic examination disclosed a sessile polypoid tumor in the ascending colon about 2.5 centimeters in diameter. Removal of the tumor was advised but the patient returned to his home.

He returned to the clinic on October 7, 1946 and at that time he did not have any symptoms that were referable to the gastrointestinal tract. Examination of the abdomen did not reveal any abnormality. Proctoscopic examination disclosed tiny polyps in the last 3 centimeters of the rectum. These tumors were fulgurated. Roentgenologic examination again revealed the polypoid tumor in the ascending colon which appeared at that time to be slightly larger than it had at the time of the patient's previous examination here.

Laparotomy was performed on November 1, 1946. The patient was rather obese and because of the presence of a large amount of fat and many epiploic tags it was not possible to determine whether or not a polyp was present in the colon. A transverse incision was made in the hepatic flexure and two Deaver retractors were inserted. A yellow polypoid tumor then popped out of the incision. It was freely movable beneath the mucous membrane. It was squeezed from its attachment, the stalk was transected and ligated with double cotton suture and the tumor was excised. The pathologist reported it to be a pedunculated submucous lipoma which measured 4 by 5 by 3 centimeters and weighed 23 grams (Fig. 1).

In a letter dated December 8, 1946 the patient stated that he was in good health.

CASE 17. A married woman aged 49 years came to the clinic in January, 1947 complaining of spells of extreme weariness and heaviness which were thought to be functional and on a menopausal basis. She complained of gas at the time of these attacks but did not have nausea or vomiting. Some blood had been noted occasionally in the stools.

On examination the patient was found to have moderate hypertension; the blood pressure ranged between 150 and 170 millimeters of mercury systolic and more than 90 diastolic. On proctoscopic examination a small polyp was found 18 centimeters from the dentate margin and this was fulgurated. Roentgenographic examinations of the stomach and gall bladder revealed nothing significant but a spot-film roentgenogram of the colon revealed a sessile, polypoid lesion about 2 centimeters in diameter, in the cecum, just below the ileocecal valve. The growth was not visible in the ordinary roentgenogram.

At operation in February, 1947, appendectomy and transcolonic removal of a lipoma 2.5 centimeters in diameter of the cecum were performed. No other abnormality was found except some fibroids of the uterus.

The convalescence was without incident and the patient was dismissed from our care on the twelfth postoperative day.

CASE 8. A woman aged 66 years, came to the clinic in March, 1947, complaining of gnawing epigastric distress which had been present for period of 8 to 10 years. Her gall bladder and appendix had been removed in 1928. She had had chronic constipation for which she habitually had used cathartics and enemas; there had not been any blood in the stools. She had not had nausea or vomiting. Her weight and general physical appearance were normal and physical examination gave essentially negative results except for mild tenderness over the upper part of the abdomen. Roentgenographic examination revealed a large diverticulum of the duodenum and some diverticulosis of the colon but did not disclose any other abnormality in the colon or terminal portion of the ileum.

Surgical treatment was advised for the duodenal diverticulum and, accordingly on March 17, 1947, resection was performed for the duodenal diverticulum. Further exploration of the abdomen revealed what appeared to be enteritis of the terminal portion of the ileum and a palpable mass in the cecum. Right hemicolectomy was performed with removal of the distal 255 feet (76.5 cm.) of ileum, the cecum, ascending colon and hepatic flexure. An end-to-end ileo-transverse colostomy was done.

Examination of the removed tissue disclosed multiple nonspecific inflammatory ulcers in various stages of healing in the terminal 5 centimeters of the ileum; perileititis had caused angulation of the ileum above the ileocecal valve and had produced mechanical obstruction. Diverticulosis was found in the colon and a submucous lipoma, 1.5 centimeters in diameter was present in the ileocecal valve.

Intermittent episodes of the intussusception might be an explanation of some of the patient's symptoms.

CASE 10. A married woman aged 53 years, came to the clinic in December, 1947, complaining of discomfort in the left lower quadrant of the abdomen of more than 5 years' duration. She had been very ill 2 weeks before admission with intermittent cramps

CARCINOID TUMORS OF THE INTESTINE

ORVILLE F. GRIMES, M.D., and H. GIFFIN BELL, M.D., F.A.C.S. San Francisco, California

ARGENTAFFIN tumors of the intestinal tract are a challenge to modern surgery because of their rarity, their altered behavior in different anatomical locations, and because in only an occasional instance has a correct diagnosis been made preoperatively. The early writers stressed the association of these tumors with obliterative appendicitis and noted that they did not infiltrate extensively and only rarely metastasized to regional lymph glands. In spite of these observations no suspicion was aroused that these were not ordinary adenocarcinomas. In 1888 Lubarsch reported 2 cases wherein multiple small separate tumors were noted in the submucosa of the terminal ileum. These consisted of columns and masses of cells which were distinctly unlike those of ordinary carcinoma. No true glandular formation was present although degeneration of some of the central cells sometimes produced a pseudoglandular appearance. Although he was well aware that these were not the usual type of carcinoma, the cases were reported as primary carcinoma of the ileum.

Oberndorfer in 1907 clarified the polemic aspects of the problem by showing that there occurred in the gastrointestinal tract in addition to the ordinary carcinomas a superficially related tumor for which he coined the term carcinoid. The important features of the latter were their localized nature and relative benignity as shown by their slow growth and lack of infiltration, the absence of metastatic spread by lymph and vascular channels, the fact that more than one tumor was often present, and their histological appearance. Oberndorfer's ideas were generally accepted but even as late as 1921 histologically similar tumors were being reported as spheroid-cell carcinoma (23).

In 1914 Gosset and Masson showed that the cells of the intestinal chromaffin tissue when stained by ammoniacal silver salts exhibited

black granules in their cytoplasm. By this method they were able to demonstrate similar cells lying among the ordinary columnar cells near the bases of the crypts of Lieberkuehn. Using similar stains they showed that carcinoid tumors were composed of cells of the same type. They therefore added the term argentaffin to these tumors. Although Masson's work is not accepted completely, there is almost general agreement that carcinoid tumors originate from the Kulchitzky cells of the crypts of Lieberkuehn. They probably should be called argentaffinomas but the term carcinoid is so deeply entrenched in medical literature that its continued use seems justifiable.

The Kulchitzky cells are more common in the appendix than elsewhere in the intestine which accounts for the high incidence of carcinoid tumors in that organ. Their incidence

Fig. The characteristic yellow submucosal tumor may obliterate the lumen and cause obstructive inflammation and necrosis of the distal appendix. The irregular lobulation caused by the fibrous tissue septa is evident. The overlying mucosa is usually intact.

From the Department of Surgery, University of California Medical School, San Francisco.

only 4 of the 12 were the lipomas removed transcolonicly.

In 3 of the 7 cases in which the lipoma was situated in the left portion of the colon segmental resection was required. In the remaining 4 cases local excision of the lipoma was performed.

A total of 11 cases out of 19 in which extensive resection for lipoma was required might appear on the surface to be a high incidence. However the difficulties encountered in making an unequivocal preoperative diagnosis, despite the improvement in roentgenologic studies, and the extensiveness of the

process of intussusception so often encountered at the time of operation play a part in influencing the surgeon to employ a more radical operation than otherwise might be indicated for a benign condition. It is interesting and significant also that despite such major surgical procedures no deaths occurred.

Table I. Appendiceal carcinoids are most often seen in young females. Growth by continuity involves successively the muscularis, the serosa, and occasionally the meso-appendix. The tumors are encountered about equally in the normal and in the acutely or chronically diseased appendix.

cells often extend beyond this, however and cell nests may be seen in the muscularis the subserosa the serosa or even in the adjacent peritoneum or mesentery (4)

The cells have round distinct nuclei but often the cytoplasmic borders are ill defined. They bear no resemblance to the ordinary columnar or mucous cells lining the intestinal glands. There is no true glandular formation. Occasionally the central portions of the cell masses exhibit a vacuole which contains an eosin staining material. This formation may closely simulate the rosettes which occur in the neuroblastomas (Fig 2)

Although the characteristic feature of the tumor as originally described was its apparent benignity it is now generally agreed that malignant change may occur. Spread occurs by continuity and contiguity of tissue as well as by invasion of lymph and vascular channels. In the small intestine such a change is rather commonly encountered. Appendiceal carcinoids however are but rarely malignant.

Fig 3. Nine (82 per cent) of the 11 appendiceal carcinoids were located in the distal portion of the appendix and only 2 in the proximal extent. Widespread abdominal involvement in 1 case may have been due to a carcinoid tumor originating in the appendix

In 1926 Stewart and Taylor reported 1 case and could find only 8 others cited in the literature. Wyatt recently has been able to collect another 5 cases.

It is becoming apparent that the behavior of the carcinoid tumors is quite different depending upon the site of the primary growth. Those arising in areas other than the appendix may appear as metastasizing malignant growths requiring radical treatment.

In the 21 year period from 1927 through 1947 19 patients were treated at the University of California Hospital for carcinoid tumors of the gastrointestinal tract. Eleven were in the appendix and 8 in the small bowel. The behavior of the tumor in each group is so different that it seems best to discuss them separately.

CARCINOID TUMORS OF APPENDICEAL ORIGIN

Appendiceal carcinoids occur usually in young people and are more commonly seen in females. The oldest patient in the University of California group was 65 the youngest 13 and the average age was 29.5 years. All were treated by simple appendectomy. One tumor was located in the proximal end 1 in the mid portion and the remaining 9 (82 per cent) were in the tip of the appendix (Fig 3). Five of the carcinoids involved the muscularis

Fig. The columns and masses of cells of the carcinoid tumor a, left are distinctly unlike those of the more common adenocarcinoma, b. There is no true glandular formation. The cells are of quite uniform size and are surrounded

by rather dense fibrous tissue stroma which tends to be condensed at the borders of the tumor. The cells have round, distinct nuclei but the cellular borders are often ill defined, a, insert

is next highest in the terminal ileum as is the incidence of carcinoids. The neoplasm grows but slowly and is often unrecognized because of its small size. In a small blind tube like the appendix it is more readily discovered than in the ileum. Of greater importance however is the possibility of appendiceal obstruction and the consequent inflammation by which attention may be drawn to it.

In spite of the rather extensive literature concerning them such tumors are rare. Although 90 per cent of all neoplasms found in the appendix are carcinoids, Foot states that only 0.46 per cent of appendices removed for appendicitis contain carcinoid tumors. A single tumor is usually present most frequently in the tip. In most of the reported series, from 70 to 80 per cent occurred in this region. Elsewhere in the gastrointestinal tract multiple tumors are more commonly encountered. After the appendix the terminal ileum is the next most common location though they may occur anywhere in the gastrointestinal tract from the cardia to the rectum and constitute about 20 per cent of all malignant tumors arising in the small intestine.

Characteristically the tumor consists of a yellow nodule of varying size which occupies the submucosa. The overlying mucous membrane is usually intact although occasionally some superficial ulceration occurs. The nodule has a firm rubbery consistency and may ex-

tend through the muscularis to involve the serosa. The cut surface of the tumor often exhibits irregular fibrous bands dividing it into more or less separate yellow nodules. In the appendix, as it increases in size the tumor may reach the opposite wall and cause obstruction of the lumen (Fig. 1). In other instances it appears as an annular thickening of the appendiceal wall frequently a centimeter or more in length which completely obliterates the lumen. In either event an attack of acute obstructive appendicitis may occur. It should be noted that the tumor obliterates the lumen not by contraction of the fibrous stroma but by its bulk. At the opposite extreme, the lesion may be so small that it is found only on microscopic examination. Elsewhere in the gastrointestinal tract, where the lesions are more often multiple, the growths usually project into the bowel lumen as smooth polypoid masses over which the mucosa is intact. A rather intense fibroplasia accompanies the invasion of the mesentery resulting in kinking of the bowel by contraction of the fibrous tissue. Occasionally the tumor assumes a ring-like constriction similar to that of adenocarcinoma.

Microscopically the tumor consists of clumps and masses of large spheroidal cells lying in a fibrous stroma. There is usually some condensation of the nonstriated muscle fibers at the periphery of the tumor in the fibrous capsule which tends to form. The

TABLE II—CLINICAL RESUMÉ OF MALIGNANT CARCINOIDS SEEN AT THE UNIVERSITY OF CALIFORNIA HOSPITAL 1927 THROUGH 1947

Case Age Sex	Symptoms and signs	Primary lesion	Metastatic deposits	Operative treatment	Postoperative treatment	Sequence
1 35 F	Abdominal pain, diarrhea, wt. loss of 40 pounds, and partial small bowel obstruction	Upper portion of ileum	Mesenteric and periaortic nodes	Biopsy and entero-enterostomy	Large bowel obstruction requiring transverse colectomy yrs. later	Died 44 mos. after enteroenterostomy with generalized abdominal metastases
2 31 F	Diarrhea, weight loss, right lower quadrant mass	Undetermined, possibly appendiceal	Omentum, peritoneum, large and small bowel, retroperitoneal tissues, pelvis	Biopsy	None	Died 6 months post operative. Generalized abdominal metastases
3 50 M	Lower abdominal pain	Terminal ileum	Adjacent mesenteric nodes	Ileocolic resection (with wide margins of mesentery)	None	N. recurrence 7 years (proved at second laparotomy for marginal ulcer)
4 41 M	Dyspepsia, anorexia, blood in stool, mass in left flank	Probably primary in jejunum	Generalized abdominal spread, including liver and spleen	Biopsy	Radiation	Died 3 mos. postoperative with generalized abdominal metastases
5 56 M	Epigastric distress, cramps, vomiting, & loss of 5 pounds. Small bowel obstruction	Terminal ileum	Adjacent mesentery by continuity	Ileotransverse colectomy (tumor not removed)	Biopsy of recurrence in abdominal wall scar	Died 50 mos. post operative with generalized abdominal metastases
6 64 F	Diarrhea, cramps, small bowel obstruction. Weight loss	Undetermined, probably terminal ileum	Mesenteric nodes, periaortic nodes, liver	Biopsy	None	Died 10 days post operative.
7 60 F	Generalized abdominal pain, diarrhea, and symptoms of small bowel obstruction	Terminal ileum	Cul-de-sac extending into vagina	Resection, and lateral anastomosis	Biopsy pelvic mass & irradiation	Died 7 years after original surgery
8 67 M	Diarrhea, intermittent abdominal pain, distention, partial large bowel obstruction	Terminal ileum	Omentum, small bowel, mesentery, peritoneum, intrahepatic metastases	Laparotomy and biopsy	None	Died 8 months after laparotomy

Table II. The average age was 58 years in the 5 males and 3 females in the series. All the tumors were malignant as shown by regional and distant lymphatic and blood borne metastases. Carcinoid tumors should no longer be regarded as clinically silent neoplasms. Operative results

are exceptionally good when it is possible to excise the tumor with a wide margin of gland bearing mesentery. Even in the presence of distant metastases a tendency toward stabilization of the metastatic deposits is noted when the primary growth is removed.

of malignant carcinoid tumors produced clinical symptoms although the majority of authors indicate a much lower percentage. It is becoming apparent that no longer should these neoplasms be regarded as clinically silent lesions. As one would suspect from the rather intense fibroplasia accompanying the mesenteric invasion obstruction results either from the kinking of the bowel by contraction of the mesentery or from intussusception occasioned by the partially intraluminal mass or masses.

Diarrhea was not only common but often severe. It is only rarely that blood can be demonstrated in the stool since the lesions usually do not cause ulceration of the mucosa. Abdominal masses were palpable in 2 patients. Their presence indicates metastatic spread since the primary lesions are almost always small (Table III)

It was true in this series as in other accounts reported in the literature that in spite of the suggestive clinical syndrome the nature of the disease was not suspected before operation. Indeed in some cases the possibility of the existence of a tumor of such nature was not entertained even at surgery. A perusal of the literature reveals that a correct diagnosis of carcinoid tumor of the bowel is made but rarely before operation. In 1942 Miller and Herrmann published the case history of a patient in whom a correct diagnosis was obtained prior to laparotomy. They indicated that in the presence of dilatation of the small bowel from carcinoid tumors a small filling defect associated with kinking of the bowel in that segment could be demonstrated roentgenologically. Coexistence of kinking and tumor of the bowel suggests the diagnosis (Fig 4)

Fig. 4. A tense fibroplasia accompanies the invasion of the mesentery by the carcinoid tumor. The results in mesenteric contraction may produce kinking of the intestine & cause obstruction. In the roentgenographic examination, the kinking of the bowel in association with an intraluminal tumor suggests the diagnosis.

only 5 involved the serosa as well as the muscularis, and 1 extended into the adjacent mesoappendix. The mucosa overlying each was intact. Four of the appendices showed acute inflammation, 3 showed submucosal fibrosis, and 4 were not abnormal. The tumors all had histologically similar characteristics even though one showed invasion of the mesoappendix. Follow up is admittedly inadequate, but there have been no reported sequelae from any of the group of patients (Table I).

Hence appendiceal carcinoids seen at the University of California Hospital conform to the generally accepted clinical and histological characteristics indicated in other reports in the literature. Patients whose appendices contain these tumors usually have no sequelae when the appendix is removed. Cell nests are seen about equally as frequently in the muscularis as in the serosa and if growth by continuity into the mesentery can be considered a criterion of malignancy then an occasional one is malignant. They are found about equally in the normal and in the acutely or chronically diseased appendix. It is probable that because of the location in a narrow blind-ending tube carcinoids of the appendix produce symptoms relatively early and are therefore removed at

an earlier stage than are similar tumors located elsewhere in the gastrointestinal tract. It may well be that in the appendix, as elsewhere, metastases and therefore malignancy are merely a matter of time. Since attention is called to the appendix early carcinoid tumors may be removed while they are still localized to that organ and for that reason the benignity of appendiceal carcinoids may be more apparent than real. Certainly the growth and histologic characteristics of the tumor in any location are identical.

CARCINOID TUMORS OF EXTRA APPENDICEAL ORIGIN

Argentaffin tumors arising elsewhere in the gastrointestinal tract present quite different problems. In this instance the tumor is likely to assume definitely malignant characteristics manifested by metastases, most of which are either to the regional lymph nodes or to the adjacent peritoneum or mesentery.

In the small intestine carcinoid tumors occur mostly in older people and the multiplicity of primary lesions is in contrast to the single primary nodule occurring in the appendix in younger age groups. In those patients in our series having carcinoid tumors of the small intestine the oldest was 67, the youngest 41, and the average age was 58 years (Table II). These observations agree with those of Cooke who in a summary of the literature noted an average age of 57.2 years in patients having malignant carcinoid tumors of the small intestine. These figures contrast markedly with the average age of 39.5 years for patients in whom appendiceal carcinoids were found. Appendiceal carcinoids were more often seen in females while small bowel carcinoids occurred in 5 men and 3 women in this group. This proportion is maintained throughout the literature.

The most common clinically observed syndrome was recurrent attacks of partial intestinal obstruction associated with pain, diarrhea, and weight loss. Five of the 8 patients with small bowel argentaffin tumors manifested this tetrad of symptoms and signs. This proportion is high in comparison with other accounts appearing in the literature. Cooke, collecting informative data from the world literature, noted that about 50 per cent

Fig 6 The predominant metastatic spread is regional involving the mesentery its nodes, and the adjacent peritoneum. Metastatic deposits were encountered in both the liver and spleen. Spread occurs by continuity and contiguity of tissue as well as by invasion of lymph and vascular channels.

all of which manifested the usual criteria of malignancy again forcefully emphasizes that carcinoid tumors of the small bowel should be considered as malignant lesions.

Because of the malignant tendencies of argentaffin tumors treatment should be as radical as is possible. It is fortunate that most of the lesions occur in the terminal ileum so that extensive resections are possible. Horsley has advocated resection of carcinoid tumors even in the presence of metastases and other authors concur for it is not unusual to see metastatic deposits become stationary after the removal of the primary growth. In the 2 cases in our series where wide resection of the tumor and gland bearing area was possible 1 patient has an apparent cure 7 years after surgery as shown by a second laparotomy for treatment of a marginal ulcer the other lived 10 years before succumbing to large pelvic metastases. Even in those cases

in which spread of the tumor made resection impossible the average survival after diagnosis of inoperability was 27 months (excluding the single mortality in the immediate postoperative period) (Table IV). It is apparent that these tumors do truly represent a challenge to modern surgery for with the possibility of early diagnosis combined with

TABLE IV —COMPARATIVE SURVIVAL OF PATIENTS OPERATED UPON

No. of patients	Operative treatment	Average time of survival
	Wide resection of tumor and mesentery	55 years
1	Enterostomostomy and biopsy	47 months
2	Biopsy only	months

Table IV. The excellent prognosis when resection is possible is quite apparent. As indicated in other accounts in the literature simple sitetracking of the lesion is advantageous. The survival time for the 6 patients in whom resection was not possible averaged 27 months.

SYMPTOMS AND SIGNS	Pain							
	Diarrhea							
	Weight loss							
	Intermittent small bowel obstructions							
	Abdominal masses							
	Blood in stool							
	Other							
	NO. OF PATIENTS	1	3	4	5	6	7	8

Table III. Pain, diarrhea, and weight loss in association with intermittent episodes of small intestinal obstruction formed the most commonly observed clinical syndrome. The presence of carcinoid tumor of the small bowel should be suspected when this tetrad of symptoms and signs is encountered. Blood is found but rarely in the stool, for these tumors usually do not cause ulceration of the mucosa. The presence of palpable abdominal masses usually indicates widespread inoperable abdominal involvement.

The lesions were primary in the ileum in 5 of the 8 patients. In 1 patient although the primary site could not be ascertained with exactitude it was strongly suspected to have been primary in the terminal ileum also. The jejunum was the primary site in 1 patient. In the remaining case, because of the widespread deposits within the abdomen it was utterly impossible to determine the site of origin. Since the distal one-third of the appendix was involved it was the opinion of the operator that the tumor could have arisen from the appendix. Our observations agree with most published reports which indicate that the

terminal ileum is the most common site of origin of carcinoid tumors of the small bowel (Fig 5).

Metastases, present in all patients, occurred most often in the regional lymph nodes, the mesentery and the adjacent peritoneum. Distant metastases were much less frequent, although metastases in the liver and spleen and even within the thorax were noted in this series (Fig 6). Once the tumor reaches the peritoneal surface of the bowel it may implant itself elsewhere just as do other malignant tumors. Axel in 1939, summarized the literature and noted that of the 237 small intestinal carcinoid tumors reported to that date only 24.9 per cent showed evidence of metastases. Dockerty and Ashburn studied 30 carcinoid tumors of the small bowel in which 13 showed undoubted evidence of metastases. This represents a percentage of 43.3 which were malignant. Humphreys in 1934 reviewed 152 cases and found 37 (24.4 per cent) that had metastases. Dangremond, reviewing 42 cases in 1942 found metastases in 24 (52 per cent).

The problem of metastases is an important one for it was only 20 years ago that Forbus emphasized the benign nature of carcinoid tumors. In recent years, however their malignant tendencies have been recognized although certainly not universally. Our group

Fig 5. Five (and probably one other) of the carcinoid tumors originated in the terminal ileum. The Kulchitsky cells from which these tumors arise are common in the terminal ileum which accounts for the high incidence in this location.

cnoid tumors may be radiosensitive. It is because of these therapeutic tangles that one should be especially alert to the possibility of the presence of carcinoid tumors. With early diagnosis and adequate resection one can expect better results in the surgical treatment of these tumors than in any other intestinal malignancy.

ANOMALOUS.—Since completion of this report, one other patient has been treated for a malignant tumor probably arising in the cecum. A white man, age 73 years, had minor episodes of generalized abdominal pain associated with diarrhea for about 1 year. Shortly before admission he noted tenderness in the right lower abdomen. He had lost 15 pounds during the year's illness. No palpable masses were noted in the abdomen but a polypoid lesion was encountered in the rectum biopsy of which demonstrated histologic evidence of malignant tumor. A filling defect in the cecum was shown by a barium enema.

Laparotomy revealed a firm mass in the cecum extending into the ascending colon. There were numerous widely scattered implants onto the peritoneum, omentum and the mesentery of both the right colon and the ileum. Nodular areas could be palpated in the liver but these were not visible on its surface. Microscopic examination of one of the implants revealed the familiar pattern of carcinoid tumor.

their relatively slow growth one would expect carcinoid tumors to be more amenable to surgical treatment than other malignant tumors of the intestine.

Prognosis depends upon the presence or absence of irremovable metastases. However even in their presence patients may live for many years after their recognition. Stewart and Taylor's patient was alive 10 years after developing metastases, and Mallory's patient lived for 20 years. This relative longevity may be attained even in those cases in which only a shortcircuited operation is possible. Terplan, Weintraub and Wolf report the case history of a patient who survived 5 years after ileocolostomy for a carcinoid tumor with hepatic metastases. The patient died by drowning 5½ years after operation. Necropsy examination showed that there was regression of the primary tumor and the hepatic metastases had remained without further growth.

Few reports have mentioned the use of radiation in the treatment of carcinoid tumors. In Ariel's case (1939) a probable metastasis in the right iliac fossa was treated by radiation with disappearance of the tumor. Bailey has suggested that the postoperative use of radiation may improve still further the relatively good prognosis of this type of intestinal tumor. Two of our patients received radiation therapy given as a palliative measure. It is impossible to draw conclusions concerning the benefits of such therapy from the observation of these patients.

SUMMARY

In addition to the ordinary adenocarcinomas, superficially related tumors known as carcinoid or argentaffin tumors also appear in the gastrointestinal tract. They occur as single nodules in the appendix but are more often multiple elsewhere in the gastrointestinal tract. In the appendix they appear in young people contrasting markedly with their appearance elsewhere in patients whose average age is 58 years. This report concerns 11 such tumors arising in the appendix and 8 whose origins were in the small intestine. Those appearing in the appendix occurred as submucosal nodules extending peripheralward to involve in succession the muscularis, the

serosa and in 1 instance the mesoappendix. All were treated by simple appendectomy after which no sequelae were noted. At the opposite extreme are the 8 patients exhibiting small bowel argentaffin tumors all of which manifested malignant characteristics as shown by local or distant metastatic spread. The similarity of histologic pattern and growth tendency leads one to believe that the tumors in either location are similar if not identical and that metastases and therefore apparent malignancy are merely a matter of time. In a small narrow blind-ending tube such as the appendix attention is called to the organ early so that the tumor is still a localized one when removed by simple appendectomy. In the small bowel such early signs as are present are most often confused with abdominal conditions not requiring immediate surgical intervention. Hence intestinal tumors are not reached at such an early stage as are those in the appendix so that metastases have had time to develop.

Carcinoid tumors of the small bowel are most often seen in the terminal ileum. Their predominant spread is regional but wide spread abdominal or distant metastases may occur just as in the more common adenocarcinomas.

Attention is called to the four most common symptoms and signs noted in carcinoid tumors of the small bowel. The tetrad of intermittent episodes of small bowel obstruction associated with abdominal pain, diarrhea and weight loss is so common and indeed quite characteristic, that consideration of such tumors is strongly advised when this syndrome appears. The roentgenological study of the small intestine in an attempt to demonstrate both kinking and tumor of the bowel is an important aid in obtaining a correct and early preoperative diagnosis.

The excellent results obtained from wide excision of the tumor bearing area cannot be too strongly emphasized. Even when distant metastases have already occurred, it is not unusual to note a tendency toward stabilization of the metastatic deposits after the primary lesion has been removed. Postoperative radiation may be beneficial for there is suggestive though incomplete evidence that car-

the lesion in respect to the peritoneal reflection were incidental and not the primary concern of their study. They therefore, did not exercise certain controls which we employed. These are (1) elimination of low-lying lesions which may affect prognosis unfavorably, (2) maintenance of uniformity of histologic grade and type of lesion (Dukes), and (3) comparison of lesions which were essentially at the same level in the bowel some of which were above and others below the peritoneal reflection.

MATERIAL AND METHODS

The material for this study was selected in such a way that all factors which might influence prognosis were controlled except the relation of the location of the lesion to the level of the peritoneal reflection.

All cases in which an adenocarcinoma of the rectum, rectosigmoid, and lower part of the sigmoid colon was removed by combined abdominoperineal resection in one or two stages, from 1916 through 1940 were selected from the files of the Mayo Clinic. From this large group, all cases in which the adenocarcinoma had been graded 2 (the Broders method, 2) by the pathologist previously examining the specimen were selected. From this group were eliminated all cases in which a metastatic lesion was demonstrable in the liver at the time of operation, those in which resection for some other reason was considered only palliative and those in which the patient died during the post-operative period of hospitalization.

In this manner, 296 cases were obtained and the formalin preserved, gross specimen removed in each of these was available for examination. Each of these gross specimens was carefully re-examined, and 137 of them were found to be suitable for inclusion in the present study. The remainder were discarded because of failure to conform to one or more of the following requisites for inclusion in this series: (1) The lesion must have been located completely above the level of the peritoneal reflection, or completely below it. Lesions lying mainly above or below this level but going over it in part were discarded. (2) The lower edge of the lesion must have been at least 2 centimeters re-

moved from the anal margin, as measured in the fixed specimen. This second requisite was adopted in order to eliminate the extremely low lying lesions whose mode of spread may differ from that of higher-lying rectal lesions and hence whose curability may differ. (3) The lesion must have been the only carcinoma in the specimen removed, multiple primary carcinomas were thus excluded. Adenomatous polyps were not considered to be carcinomas and thus their presence did not eliminate a case from inclusion in the study. (4) Enough of the gross specimen must have been present to allow adequate identification of the peritoneal reflection measurement of the distance from the lower edge of the lesion to the anal margin and selection of tissue for microscopic examination from the lesion and from the regional lymph nodes. Only a few cases were eliminated because the specimen failed to meet this last specification.

Each of the 137 gross specimens finally selected was carefully examined and a sketch was made of each. The size of the carcinoma and its situation with respect to the level of the peritoneal reflection and to the anal margin were noted. Incisions from the serosal surface or from that of the fascia propria to the mucosal surface were made transversely to the long axis of the bowel at intervals of approximately 0.5 centimeter. These thin slices hinged on the uncut mucous membrane and greatly facilitated the search for involved lymph nodes. Each specimen was carefully dissected for such nodes, and any that were suspected of being involved were removed and transferred to bottles containing a fresh 10 per cent solution of formalin. These specimens were subsequently sectioned with the freezing microtome cut at 10 microns thickness stained in the routine manner with hematoxylin and eosin, and examined microscopically for the presence of metastatic carcinoma. The primary growth was cut across through its most deeply ulcerated part, and note was made whether it had involved perirectal fat or had penetrated the serosa. Sections were then taken from the deepest extent of the growth, from all regions of apparent subserosal or serosal infiltration,

THE ROLE OF THE PERITONEAL REFLECTION IN THE PROGNOSIS OF CARCINOMA OF THE RECTUM AND SIGMOID COLON

JOHN W. KIRKLIN, M.D., MALCOLM B. DOCKERTY, M.D. and
JOHN M. WAUGH, M.D., F.A.C.S. Rochester, Minnesota

ALTHOUGH studies on the factors affecting the prognosis of carcinoma of the rectum and lower part of the sigmoid colon are not new the present availability of a number of operative procedures for lesions in this region has stimulated increased thought and attention to these factors. Segmental resection with end-to-end anastomosis (3-15) modifications of the Hochenegg pull through procedure (1) and low segmental resection with anastomosis through the sacral or perineal approach (11-13) all have now appeared to challenge the classical combined abdominoperineal resection for carcinoma in this region. These procedures preserve function of the anal sphincter to some degree at least and do not necessitate a permanent abdominal colostomy.

An accurate appraisal of the merits of these procedures and the indications for their employment depends on several considerations. Differences in operative mortality must of course be ascertained. The adequacy of function of the sphincter when these procedures are used and the merits of such function in comparison with a colonic stoma should be known. An understanding of the factors affecting prognosis in cases of carcinoma of the rectum and lower part of the sigmoid colon is of fundamental importance in the selection of a curative operative procedure. Although there are many such factors, we are concerned here with only one of these namely the relation of the location of the growth to the level of the reflection of

the pelvic peritoneum from the wall of the bowel.

Some surgeons consider that the prognosis when lesions lie below the peritoneal reflection is inherently poorer other factors being equal than when lesions lie above this reflection in a portion of bowel covered by serosa. Thus these same surgeons tend to employ a more radical procedure usually combined abdominoperineal resection, for lesions below the peritoneal reflection although other factors might have permitted a procedure which allowed preservation of the anal sphincter.

It thus seemed of value to determine whether or not the location of the lesion with reference to the peritoneal reflection has any influence on the prognosis in cases of carcinoma low in the sigmoid colon and high in the rectum. A careful review of the literature failed to reveal a single study of this matter. Therefore the present investigation was undertaken.

Since this project was completed however the most recent of the careful studies on carcinoma of the intestine carried out by Gilchrist and David has been published. These authors found that in their cases colonic carcinoma situated partially or completely below the peritoneal reflection had a relatively high incidence of recurrence and metastasis, and thus that in their group the prognosis in such cases was poorer than in cases in which the lesions were completely above the peritoneal reflection. It might seem from this that the location of the growth in relation to the peritoneal reflection does have an effect on prognosis.

Close study of the report of Gilchrist and David revealed however that their findings with regard to the effect of the location of

TABLE III—CARCINOMAS 5 6 OR 7 CENTIMETERS ABOVE ANAL MARGIN FIVE YEAR SURVIVAL RATES

Site of lesions	Patients studied	Patients traced	Lived 5 or more years after operation	
			Patients	Per cent of patient traced
Above the peritoneal reflection	20	6	7	43.8
Below the peritoneal reflection	4	4	6	40

At a variable level the peritoneum is reflected off the lateral surfaces of the rectum to the sides of the pelvis and from the anterior surface of the rectum to the bladder in the male and to the posterior vaginal wall in the female (12). The anterior reflection is of course higher in the male than in the female and is at a variable height from the anal margin in both.

The level of the peritoneal reflection is an arbitrary point to a certain extent. This is inevitable because of the anatomic features previously mentioned which are illustrated in Figure 1. It seemed wise in this study to consider the point of lateral reflection of the peritoneum to the pelvic wall as the level of the peritoneal reflection although in many instances the peritoneum did dip lower than this on the anterior surface of the rectum. This lateral reflection was in nearly every instance definite and its site could be identified easily. Its employment as the level of peritoneal reflection gave results which could be reproduced accurately.

In the specimens studied this level of peritoneal reflection was from 5 to 10 centimeters above the anal margin which is in good agreement with the classic description of this region (10).

RESULTS

Of the patients traced who had lesions above the level of the peritoneal reflection 54.4 per cent survived 5 years or more after operation and 59.4 per cent of those whose lesions were below the level survived 5 years (Table I). Both groups of patients had undergone combined abdominoperineal resection. The difference in the 5 year survival rates is

Fig. 2 Site of the lesion with reference to the anal margin in the two groups of cases studied.

probably not significant and thus the prognosis in the entire series of cases in which the lesion is located above the level of the peritoneal reflection is entirely comparable to that in cases in which it is below it.

In Table II are presented the 5 year survival rates of the groups of patients with lesions above and below the level of the peritoneal reflection broken down according to the slight modification of the Dukes method of typing previously described. It is apparent from these data that type for type the prognosis in cases in which the lesions are above the level of the reflection is entirely comparable with the prognosis when the lesions are below the reflection. This is further strong evidence to support the conclusion derived from this study that the location of the lesion with reference to the peritoneal reflection has no effect on the prognosis.

Before this conclusion was accepted it had to be established with as much certainty as possible that variation in location of the lesions in the two groups with reference to the anal margin did not influence the results. In order to establish this point the data were analyzed further.

The distance from the lower edge of the lesions to the anal margin as measured in the fixed specimens in the two groups of cases is shown in Figure 2. Because of the marked variation in the level of the peritoneal reflection from the wall of the low part of the sigmoid colon and rectum as previously mentioned there was some overlapping be-

Fig. 1. The peritoneal covering of the rectum and lower part of the sigmoid colon. A growth at the location that here has relatively little opportunity for direct access to the rectum, even though it lies above the level of the peritoneal reflection.

and from any region of perirectal spread. These specimens were transferred to bottles containing a fresh 10 per cent solution of formalin and were sectioned and stained as previously mentioned. These sections were then examined for confirmation of the grading according to the method of Broders and for typing according to a modification of the method of Dukes. Microscopic evidence of actual serosal penetration in contrast to mere subserosal infiltration was sought. By this review 6 cases were eliminated because of a previous error in grading them as grade 2 which left 131 cases in the final group.

The method of typing employed was a slight modification of the Dukes method (5). The criteria employed were as follows: type A lesion limited to the mucosa; type B₁ lesion extended into the muscularis propria but did not penetrate through it; type B₂,

TABLE I.—COMPARISON OF FIVE YEAR SURVIVAL RATES IN CASES OF CARCINOMA SITUATED ABOVE AND BELOW THE LEVEL OF THE PERITONEAL REFLECTION

Site of lesion	Patients studied*	Patients traced	Lived 5 or more years after operation	
			Patients	Per cent of traced patients

lesion penetrated through the muscularis propria and type C lesion of either type B₁ or B₂ with involvement of lymph nodes.

The clinical history and the follow-up correspondence in all cases were reviewed. The cases were separated into two groups, one in which the lesions were located above the level of the peritoneal reflection and the other in which the lesions were located below this level. The data thus obtained were compared.

ANATOMIC CONSIDERATIONS

The sigmoid colon is covered by peritoneum except for the narrow mesenteric attachment low in the sigmoid colon. This mesenteric attachment gradually becomes broader and in the region of the sigmoid-rectal junction may occupy nearly half the circumference of the intestinal wall. Because of this, the upper portion of the rectum is devoid of peritoneal covering on its posterior surface while the lateral and anterior surfaces are covered with peritoneum (4, 10, 12).

lesion penetrated through the muscularis propria and type C lesion of either type B₄ or B₅ with involvement of lymph nodes.

The clinical history and the follow up correspondence in all cases were reviewed. The cases were separated into two groups, one in which the lesions were located above the level of the peritoneal reflection and the other in which the lesions were located below this level. The data thus obtained were compared.

ANATOMIC CONSIDERATIONS

The sigmoid colon is covered by peritoneum except for the narrow mesentery at attachment low in the sigmoid colon. This mesenteric attachment gradually becomes broader and in the region of the sigmoid-rectal junction may occupy nearly half the circumference of the intestinal wall. Because of this, the upper portion of the rectum is devoid of peritoneal covering on its posterior surface while the lateral and anterior surfaces are covered with peritoneum (4, 10, 12).

TABLE II—COMPARISON OF FIVE YEAR SURVIVAL RATES IN CASES OF CARCINOMA SITUATED ABOVE AND BELOW THE PERITONEAL REFLECTION ACCORDING TO TYPE (DUKES) OF LESION

Type	Lesions above the level of the peritoneal reflection				Lesions below the level of the peritoneal reflection			
	Patients studied	Patients traced	Lived 5 or more yr. P. O.		Patients studied	Patients traced	Lived 5 or more yr. P. O.	
			Patients	Per cent of traced patients			Patients	Per cent of traced patients
A								100
B ₁	5		5		5	3	6	71
B ₂		20	20		36	33	5	64.7
C	24	2	26.4		4		2	50

tween the two groups at certain levels. Thus some of the lesions situated 5, 6 and 7 centimeters above the anal margin were completely above the peritoneal reflection and others were completely below it. Due to this fortunate occurrence it was possible in a small group of cases in which the lesions were at essentially the same level in the rectum to compare the prognosis when the lesions were located above the reflection with that in cases in which they were located beneath it. As shown in Table III such a comparison indicated that there was no significant difference in the 5 year survival rate in the two groups. This observation substantiates the conclusion that the location of the lesion with respect to the level of the peritoneal reflection does not affect prognosis following radical combined abdominoperineal resection for carcinoma of the rectum and lower part of the sigmoid colon.

It should be noted that there is no justification for drawing conclusions as to the significance of the relatively low survival rate in cases in which lesions were 5, 6 and 7 centimeters from the anal margin. The method employed in selecting the cases for this study controlled factors pertinent to this analysis but did not control factors pertinent to a study of the effect of the level of the lesion on prognosis. An investigation of this effect is being made at present.

COMMENT

The present difference of opinion as to the surgical procedures of choice in dealing with carcinoma of the lower part of the sigmoid colon and rectum makes necessary the accumulation of all possible pertinent data. It is, of course, true that when each procedure has been carried out a significant number of times in comparable cases, and the patients have been followed for a period long enough to insure reliable survival rates, a comparison of these rates will give a reasonable insight into the relative efficacy of these procedures.

However the difficulties inherent in the comparison of statistical material obtained from different sources in the literature are well known. Operability rates, operative mortality rates and types of lesions as well

as the location of lesions all influence the over all 5 year survival rate and all are rarely given in the reports. Furthermore unless the series are actually comparable in all respects and all factors which may produce variation in prognosis in and of themselves are controlled comparison of different statistical analyses is valueless. For example the comparison of the 5 year survival rates after anterior resection with those after combined abdominoperineal resection is valid only if the groups of cases in which these two procedures have been employed are entirely comparable. Obviously to begin with, the investigator must be certain that the 5 year survival rate in cases in which the lesions are high in the rectum or low in the sigmoid colon (that is lesions suitable for anterior resection) and are removed by combined abdominoperineal resection is entirely comparable to that for the entire group treated by abdominoperineal resection. If the survival rate in cases of high-lying lesions is better after combined abdominoperineal resection than is the survival rate in cases of low lesions after the same procedure then the 5 year survival rate following anterior resection must be compared not to that for the total group of patients treated by combined abdominoperineal resection but to that of the patients who had lesions at the same level as those treated by anterior resection.

Thus, in order to compare statistical data obtained from the various operative procedures with regard to survival rates alone the data must be as complete as possible on the factors affecting the prognosis. Furthermore when these factors in prognosis are recognized and the manner of growth and spread of such lesions are understood the surgeon can feel more secure in adopting a particular method of surgical management without awaiting the accumulation of data in sufficient quantity to give survival rates of undoubted significance.

It has been clearly demonstrated (14) that the microscopic appearance of the carcinomatous cells reflected in the Broders system of grading is one factor which must be considered and controlled in comparing statistical results. The choice of a surgical pro-

cedure in a given case is rarely influenced by this factor however. The type of the lesions according to the Dukes method of typing is of prognostic significance (6) and must be controlled in comparisons of statistical data again this is rarely known pre-operatively and thus unfortunately is of little value to the surgeon in choosing an operative method in a given case (9). It is probable that the location of lesions in the rectum and lower part of the sigmoid colon with reference to their distance from the anal margin exerts an influence on prognosis. It is then one further factor which must be controlled in comparisons of statistical data and which must be taken into account in the choice of the surgical procedure to be employed in a given case. The method of lymphatic spread is of utmost importance in the choice of an operative procedure (8) but since it is relatively constant for lesions in the same location it is not a factor that need be controlled in comparisons of statistical data provided the previously discussed factor of location is controlled.

Since some lesions of the rectum and lower part of the sigmoid colon lie above the level of the peritoneal reflection and some lie below this level the relation of the lesion to the peritoneal reflection is a further factor

which should be understood with reference to prognosis and with reference to the selection of a curative operative procedure. It is demonstrated in this study that the location of the lesion with reference to the level of this peritoneal reflection has no effect on prognosis.

Thus in comparisons of statistical material and in the selection of an operative procedure in a given case this factor may be ignored.

CARCINOMA OF THE ENDOMETRIUM IN YOUNG WOMEN

HAROLD SPIERT, M.D., New York, New York

NO woman regardless of age is immune to uterine cancer. Carcinoma of the cervix although rare in young girls is fairly common in women of 40 or younger. At the Roosevelt Hospital 27 per cent of all patients with cancer of the cervix were under 41 years of age. Cancer of the corpus on the other hand is regarded as extraordinary in women of this age group. Donald and Shaw (1929) have expressed the opinion that with the rarest exceptions cancer of the body of the uterus does not begin in subjects under 40 years of age or alternatively until after the retrogressive changes of the menopause have set in. Present experience however suggests that even fundal neoplasms in young women may be not so rare as is generally believed. The literature contains numerous references to individual cases of cancer of the corpus in children (Hirst 1929, Kehrer and Neumann 1929, Gilbert 1932, Lockhart 1935), young girls (Smith 1933, Mazzola 1938, Healy and Brown 1939, Morrin and Max 1939) and women in their early thirties (Purdie 1945, Bianchi 1946, Taylor and Becker 1947, Driesen 1947). In a recent tabulation of 255 cases of primary carcinoma of the endometrium 12 patients (4.6 per cent) were under age 41 (Speert 1948). Two additional cases of cancer of the corpus in young women which have come to light since then make our incidence of women with this disease in the first 4 decades of life about 5 per cent. These 14 cases form the basis of the present report.

Some of the salient clinical and pathological features of the cases are summarized in Table I. From their study emerges evidence in support of the theory that continuous and unopposed estrogenic stimulation is a factor in the pathogenesis of endometrial carcinoma.

Fertility. The group as a whole showed a remarkably low degree of fertility. Eight of the patients (57 per cent) had never borne children. This percentage is slightly higher

than the incidence of nulliparas among all our patients with endometrial carcinoma (41 per cent). The average parity of the 14 patients was only 0.57 in comparison to 1.34 for all patients with cancer of the corpus and 2.83 for those with cancer of the cervix. It is a striking fact that although all 14 patients were of child bearing age the most recent pregnancy among them had occurred 14 years previously.

Ovaries. Description of the ovaries is based on restudy of the histologic sections when available. In the other cases on the recorded pathological reports. In 8 cases the ovaries were described as cystic, in 1 as sclerotic, and in 1 as hyaline. Routine sections of the majority of the ovaries contained no evidence of ovulation. In only 2 cases were recent corpora lutea seen. Counseller (1938) has also been impressed with this negative correlation, stating that he had never seen a carcinoma of the fundus in which there was not also a failure or inactivity of the corpus luteum. An interesting feature present in several of the present cases was an unusually thick tough, fibrous tunica albuginea (Figs. 2 and 5). This may possibly have acted as a mechanical barrier to ovulation as suggested by Babes (1924) and others. Theca cell hyperplasia was described in 1 case. Two patients had had an ovary removed previously because of benign cysts.

Endometrium. The uninvolved parts of the endometrium reflected the absence of luteal activity. In no instance was a secretory type of endometrium encountered. This differs sharply from the experience of Jones and Brewer (1941) who described a secretory endometrium in 8 of 19 premenopausal patients with fundal carcinomas. On the contrary endometrial hyperplasia was present in at least 5 of our patients. In 1 instance (Case 3) hyperplasia was probably of long standing since it had also been diagnosed by curettage 6 years before. Another patient (A. C. Table I) had had treatment with intrauterine radium 16 years previously because of functional bleeding which

Fig. 1 Case 1. Adenocarcinoma in hyperplastic endometrium of patient aged 33 years.

Fig. 2 Case 1. Section of ovary showing thick, fibrous tunica albuginea.

was associated with endometrial hyperplasia.

Cervix. Squamous metaplasia resulting in epidermidization of the endocervical glands was seen in routine sections of 5 of the removed cervixes. Since 2 cervixes were not described, 1 was not removed, 1 was invaded by the endometrial tumor, and 1 showed a radiation reaction, the incidence of cervical epidermidization in the 9 remaining cases was 56 per cent. The possible significance of this lesion as a manifestation of abnormal estrogenic stimulation has been discussed in another paper (Speert 1948).

Three cases reported herewith in detail exemplify the combination in young women of endometrial hyperplasia, endometrial carcinoma, cystic ovaries with thick tunics and no corpora lutea, and epidermidization of the cervix.

CASE 1. F. W., a 33 year old colored nulliparous divorcee, was admitted to the hospital on February 6, 1947, for curettage because of menorrhagia. Her menses had always been irregular, long periods of amenorrhea up to a year alternating with periods of bleeding lasting a week to a month. Her last flow occurred in mid-December 1946, the current flow began January 16, 1947. Examination was negative. Basal metabolic rate was -16 . Uterine curetting showed endometrial hyperplasia and adenocarcinoma, grade 1 (Fig. 1). On February 11, total hysterectomy and bilateral salpingo-oophorectomy were performed. The ovaries were large, white and smooth and each was encased in a tough, thick tunica albuginea (Fig. 2). Immediately subjacent to this capsule were numerous small follicular cysts. There was no histologic evidence that either ovary had ever

ovulated. Section of the cervix showed epidermidization of the glands (Fig. 3).

This is an excellent example of polyhormonal amenorrhea (Zondek 1934) alternating with periods of menorrhagia. The associated hyperplasia of the endometrium, a presumably long standing response to continuous unopposed estrogenic stimulation, was the apparent forerunner of a grade 1 adenocarcinoma.

CASE 2. M. H., a 22 year old white single patient of Dr. William P. Healy, had suffered for several years with irregular intermenstrual bleeding. Various types of endocrine therapy had failed to control this bleeding. Curettage on June 13, 1944, produced a profusion of tissue which was diagnosed as hyperplasia. The patient's periods became regular for 8 months. Intermenstrual bleeding then returned occurring daily for about 3 months prior to her readmission on January 8, 1947. Another curettage again brought forth voluminous scrapings. Diagnosis this time was endometrial hyperplasia and adenocarcinoma, grade 1. When the section of the original curettings was now reviewed, a similar type of car-

Fig. 3 Case 1. Epidermidization of cervical glands.

CARCINOMA OF THE ENDOMETRIUM IN YOUNG WOMEN

HAROLD SIFFERT M.D. New York, New York

NO woman regardless of age is immune to uterine cancer. Carcinoma of the cervix although rare in young girl is fairly common in women of 40 or younger. At the Roosevelt Hospital 27 per cent of all patients with cancer of the cervix were under 41 years of age. Cancer of the corpus on the other hand is regarded as extraordinary in women of this age group. Donald and Shaw (1929) have expressed the opinion that "with the rarest exception cancer of the body of the uterus does not begin in subjects under 40 year of age or alternatively until after the retrogressive changes of the menopause have set in." Present experience however suggests that even fundal neoplasms in young women may be not so rare as is generally believed. The literature contains numerous references to individual cases of cancer of the corpus in children (Hirst 1929, Kehrer and Neumann 1909, Gilbert 1932, Lockhart 1935) young girls (Smith 1933, Mazzola 1938, Healy and Brown 1939, Morrin and Max 1939) and women in their early thirties (Lunlie 1945, Bianchi 1946, Taylor and Becker 1947, Driessen 1947). In a recent tabulation of 235 cases of primary carcinoma of the endometrium 12 patients (4.6 per cent) were under age 41 (Speert 1948). Two additional cases of cancer of the corpus in young women which have come to light since then make our incidence of women with this disease in the first 4 decades of life about 5 per cent. These 14 cases form the basis of the present report.

Some of the salient clinical and pathological features of the cases are summarized in Table I. From their study emerges evidence in support of the theory that continuous and unopposed estrogenic stimulation is a factor in the pathogenesis of endometrial carcinoma.

Fertility. The group as a whole showed a remarkably low degree of fertility. Eight of the patients (57 per cent) had never borne children. This percentage is slightly higher

than the incidence of nulliparas among all our patients with endometrial carcinoma (41 per cent). The average parity of the 14 patients was only 0.57 in comparison to 1.34 for all patients with cancer of the corpus and 2.83 for those with cancer of the cervix. It is a striking fact that although all 14 patients were of child bearing age the most recent pregnancy among them had occurred 14 years previously.

Ovaries. Description of the ovaries is based on restudy of the histologic sections when available in the other cases on the recorded pathological reports. In 8 cases the ovaries were described as "cystic in part as sclerotic" and in 1 as hyaline. Routine sections of the majority of the ovaries contained no evidence of ovulation. In only 2 cases were recent corpora lutea seen. Counseller (1938) has also been impressed with this negative correlation stating that he had never seen a carcinoma of the fundus in which there was not also a failure or inactivity of the corpus luteum. An interesting feature present in several of the present cases was an unusually thick tough fibrous tunica albuginea (Figs. 2 and 5). This may possibly have acted as a mechanical barrier to ovulation as suggested by Babes (1924) and others. Theca cell hyperplasia was described in 1 case. Two patients had had an ovary removed previously because of benign cysts.

Endometrium. The uninvolved parts of the endometrium reflected the absence of luteal activity. In no instance was a secretory type of endometrium encountered. This differs sharply from the experience of Jones and Brewer (1941) who described a secretory endometrium in 8 of 19 premenopausal patients with fundal carcinomas. On the contrary endometrial hyperplasia was present in at least 5 of our patients. In 1 instance (Case 1) hyperplasia was probably of long standing since it had also been diagnosed by curettage 6 years before. Another patient (A C Table I) had had treatment with intrauterine radium 16 years previously because of functional bleeding which

The patient's periods became regular for 8 months. Intermenstrual bleeding then returned, occurring daily for about 3 months prior to her readmission on January 8, 1947. Another curettage again brought forth voluminous scrapings. Diagnosis: this time was endometrial hyperplasia and adenocarcinoma, grade 1. When the section of the original curettings was now reviewed, a similar type of car-

Fig. 3 Case 1 Epidermidization of cervical glands.

Fig. 4. Case 1. Adenocarcinoma in hyperplastic endometrium of patient aged 35 years.

omatous change was discovered. The gross and microscopic findings in the endometrium (Fig. 4), ovaries (Fig. 5), and cervix (Fig. 6) of this patient were similar to those in Case 1.

This case illustrates the importance of investigating by curettage abnormal bleeding

Fig. 5. Case 3. Section of ovary showing tunica albuginea.

Fig. 6. Case 2. Microscopic section also showed epidermalization of cervical glands.

even in young women before resorting to hormonal therapy. Scheffey, Farrell and Hahn (1945) have reported 7 cases in which uterine cancer was overlooked because estrogens were used for irregular bleeding without preliminary curettage. Our recent records include several additional cases in which the same error was committed.

CASE 3. C. M., a tremendously obese (360 pounds) 37 year old white woman with a child of 14 years, was admitted February 10, 1947 because of menorrhagia. For 3 years her periods had lasted 10 to 14 days and for the past 6 weeks an irregular flow was observed every 2 to 4 days. Curettage had been performed 6 years previously for the same type of complaint with the curettings showing atypical hyperplasia. Curettage was repeated on February 12, 1947. Pathological report on the scrapings: "endometrial hyperplasia with early carcinoma." The uterus and adnexa were removed a week later. The ovaries were cystically enlarged to a maximum diameter of 7 centimeters. Their tunics were smooth, tough, and fibrous, and measured up to 4 millimeters in thickness. There was no anatomical evidence of recent ovulation. Section of the endocervix also showed epidermalization of the glands.

This case is a further example of carcinomatous change in a pre-existing hyperplastic endometrium. The interval of almost 6 years between the 2 curettings indicates the slowness of the malignant transformation. In another case (A. C. Table I) a patient of 37-16 years had elapsed between the original diagnosis of hyperplasia and the subsequent detection of adenocarcinoma. Mazzola (1938) has also re-

ported a case of endometrial carcinoma in a young girl 12 years after the first of several curettages and radium applications for recurrent hyperplasia

DISCUSSION

This paper is designed to emphasize three main points. First carcinoma of the endometrium although typically a disease of middle age is not as rare in young women as is generally believed. Approximately 5 per cent of all cases of cancer of the corpus at the Roosevelt Hospital have been in women not over 40 years old. The second point is a corollary to the first. Abnormal uterine bleeding not associated with pregnancy merits curettage in addition to any other type of investigation regardless of the patient's age. Not only will an occasional unsuspected uterine carcinoma be discovered in young women in this manner but curettage alone affords temporary or permanent cure in many cases of functional bleeding. Hormonal therapy without preliminary curettage is unsound. Finally the cases which form the basis of this report suggest that women who develop endometrial cancer within the first 4 decades of life conform in general to a specific hormonal pattern characterized by long continued and unopposed estrogenic activity. This is indicated by their low fertility and the

high incidence among them of endometrial hyperplasia, cystic ovaries with no evidence of recent ovulation and epidermidization of the cervical glands.

A recent study by Novak and Rutledge (1948) has called attention to certain atypical benign lesions of the endometrium sometimes encountered in young women which may simulate adenocarcinoma. In the light of their work one might naturally ask whether the cases herein reported were instances of genuine cancer. Only 1 of our patients is known to have died of the disease. In another metastatic tumor was present in the ovaries. In the remaining dozen cases the diagnosis rested on the opinion of the pathologist corroborated in a few instances by consultation with another pathologist. Recent restudy of the sections has substantiated the original diagnosis in each instance.

SUMMARY

1. Fourteen cases of endometrial carcinoma in women 40 years of age or under are reported. About 5 per cent of all corpus cancers at the Roosevelt Hospital were in this age group.

2. These cases were characterized by a high incidence of infertility, hyperplasia of the endometrium, cystic ovaries without recent ovulation and epidermidization of the cervical glands.

Fig. 4. Case 1. Adenocarcinoma in hyperplastic endometrium of patient aged 39 years.

cinomatous change was discovered. The gross and microscopic findings in the endometrium (Fig. 4), ovaries (Fig. 5), and cervix (Fig. 6) of this patient were similar to those in Case 2.

This case illustrates the importance of investigating by curettage abnormal bleeding

Fig. 6. Case 2. Microscopic section also showed epidermidization of cervical glands.

even in young women before resorting to hormonal therapy. Scheffey, Farrell, and Hahn (1945) have reported 7 cases in which uterine cancer was overlooked because estrogens were used for irregular bleeding without preliminary curettage. Our recent records include several additional cases in which the same error was committed.

CASE 3. C. M., a tremendously obese (260 pounds) 37-year-old white woman with a child of 14 years, was admitted February 10, 1947, because of menometrorrhagia. For 2 years her periods had lasted 1 to 14 days and for the past 6 weeks an irregular flow was observed every 1 to 4 days. Curettage had been performed 6 years previously for the same type of complaint with the curettings showing atypical hyperplasia. Curettage was repeated on February 12, 1947. Pathological report on the scrapings was endometrial hyperplasia with early carcinoma. The uterus and adnexa were removed a week later. The ovaries were cystically enlarged to a maximum diameter of 7 cm. Their tunics were smooth, tough, and fibrous, and measured up to 4 millimeters in thickness. There was no anatomical evidence of recent ovulation. Section of the endocervix showed epidermidization of the glands.

This case is a further example of carcinomatous change in a pre-existing hyperplastic endometrium. The interval of almost 6 years between the 2 curettings indicates the slowness of the malignant transformation. In another case (A. C. Table I) a patient of 37 1/2 years had elapsed between the original diagnosis of hyperplasia and the subsequent detection of adenocarcinoma. Maxxola (1938) has also re-

EVALUATION OF THE VARIOUS CLINICAL SIGNS OF THROMBOPHLEBITIS AND EXPERIENCE IN THERAPY WITH ANTICOAGULANTS

DAVITT A. FELDER, M D., Minneapolis Minnesota

ALL patients with thrombophlebitis of the lower extremities in the University of Minnesota Hospitals from May, 1945 to January 1948 have been personally examined and followed by the author. These 92 cases represent 105 extremities with deep thrombophlebitis and in some instances with superficial thrombophlebitis as well. The majority of these patients were treated with anticoagulants. We believe that the bland and the inflammatory venous thromboses of the lower extremities may practically all be called thrombophlebitis. In our hospital for the period of our study the incidence of thrombophlebitis was 92 cases in a total of 14 116 or 0.65 per cent.

DIAGNOSIS

This study is in part an attempt to evaluate the usual diagnostic signs and symptoms of thrombophlebitis of the lower extremities. In order to be reasonably sure of the diagnosis of thrombophlebitis we have included in this report only those cases in which at least three of the following signs and symptoms were present: swelling, vessel tenderness, pain, increased temperature in the limb, dilated superficial veins (unilateral), cyanosis (unilateral), pulmonary embolism (reasonably proved) and change in temperature and pulse (otherwise unexplained). Those cases in which unilateral swelling alone was found or pulmonary embolism alone without leg symptoms were followed but not included in this series. In 3 instances, patients with pulmonary embolism alone developed symptoms of thrombosis in 4 to 5 days and so were included in the study.

Swelling was the most frequent symptom in this series. It occurred in 93 or 88.5 per cent of the extremities. It was accompanied by tenderness in 60 extremities and by heat in only 42 instances. Swelling, heat and tender-

ness occurred in 35 extremities. In most instances, swelling was quite apparent but in some cases could be determined only by measurement. Swelling of the genitalia usually occurs when there is involvement of the common iliac vessels occluding the hypogastric vein or higher. There were 6 instances of swelling of the genitalia. In 3 instances involvement of the iliac vessels was proved at postmortem examination.

Tenderness was the symptom next in frequency to swelling. It occurred in 79 or 75 per cent of the extremities.

Deep calf tenderness is elicited by pressing between the gastrocnemius muscle bellies in the calf (Fig. 1). It was found to be the most frequent and consistent of deep vessel signs being present in 70 or 66.5 per cent of the extremities examined.

Calf squeeze tenderness is elicited by gently squeezing the calf from side to side (Fig. 2). Its value has been stressed by Moses. While probably not as significant as deep calf tenderness it is an important maneuver in substantiating deep vein involvement when used with the deep calf pressure. It was found in 56 or 53 per cent of the extremities. Calf squeeze and deep calf tenderness together occurred in 50 or 45.5 per cent of the extremities.

Homans' sign is the presence of pain in the calf elicited by passive dorsiflexion of the foot (Fig. 3). In all of these maneuvers for deep vein tenderness one must remember to keep the knee flexed thereby relaxing the calf muscles. This sign was found to be positive in 52 or 49.5 per cent of the extremities. Aside from the fact that this sign is the least frequent of those mentioned here we believe that it is much less reliable for routine examination because of the great possibility of its being positive in the presence of simple muscle involvement alone. It involves mostly muscle stretch

From the Department of Surgery, University of Minnesota.

3 Continuous unopposed estrogenic stimulation is an important factor in the pathogenesis of endometrial carcinoma.

4 Persistent abnormal uterine bleeding deserves curettage regardless of the patient's age.

Fig. 3. Homans' maneuver of passive dorsiflexion of the foot to elicit calf pain.

Dilated superficial veins The presence of dilated superficial veins is sometimes of use in making a diagnosis of deep vein thrombosis. This finding was noted in only 3 cases in this series. It probably is indicative of thrombosis above the common femoral when the long saphenous bears a great burden of the venous drainage or when its entrance into the femoral is also occluded so that the pressure in it is elevated. This dilatation disappears as soon as ample additional collaterals are established with bed rest in the Trendelenburg position and with the administration of anticoagulants this ordinarily has taken no longer than 48 hours. From our experience with patients studied prior to this series and subsequent to it, we believe that dilatation of the superficial vessels occurs at least twice as often as recorded here.

Level of thrombosis It has been claimed by Birger and Bauer (5) that if one could stop a thrombosis from progressing above the popliteal level patients could be assured of a much brighter future as far as complicating factors such as persistent edema and stasis changes are concerned. An attempt was made to determine the level of thrombosis clinically. When a patient was found to have ankle or leg edema, it was thought, unless there was indicative tenderness higher that the patient's level of thrombosis was probably the posterior tibial vein. The thrombus might extend into the popliteal vein or higher but was probably not occluding its lumen. There were 58 such extremities the left leg being more often involved than the right.

Sural vein thrombosis The sural veins drain the posterior muscle group of the leg (Fig. 4)

Fig. 4. Example of sural vein distribution (from dissections on amputated extremities by the author)

In 2 cases a simple sural vein thrombosis was found with surrounding induration of the calf. These thrombi can often be felt on one or both sides of the upper calf just below the knee. Sural vein thrombosis should not be treated lightly and is as important as any other deep thrombophlebitis or thrombosis for such thromboses generally progress to involve the popliteal vein and upward. Many of our patients with deep thrombosis had induration of the calf probably due to a blocking of the sural veins as they enter the popliteal.

There were 41 instances in which swelling of the thigh and legs usually with femoral vein tenderness up to the inguinal fold, was considered as an indication of iliofemoral thrombosis with the thrombosis either at a femoral or external iliac level.

In the patients with swelling and tenderness above the inguinal fold into the lower abdomen and in some cases involving the genitalia (swelling) the level of the thrombus was assumed to be iliac. With swelling of the genitalia, the level was assumed to be at the common iliac with involvement or occlusion of the hypogastric.

That clinical impressions can be grossly in correct in this disease was proved by 2 patients in whom clinically the level of the thrombosis was found to be at the posterior tibial and femoral veins respectively. At op-

Fig. 1. Maneuver to elicit deep calf tenderness.

Fig. Calf-squeeze maneuver

ing and deep vein pressure only secondarily whereas the calf squeeze and especially the deep calf maneuvers involve more direct pressure over the vessels in question (mainly the posterior tibial and calf veins where most thromboses probably begin)

Popliteal tenderness was found in only 17 instances, never without other tenderness. This would lead one to believe that it is of limited value as a diagnostic sign.

Anterior tibial tenderness was found in only 2 instances. Involvement of the anterior tibial veins in thrombosis is not frequent but has been found to be present in a number of instances. This was indicated by fairly definite venographic studies done by the author in patients with chronic deep thrombophlebitis and in a few of the cases in this series. The infrequency of anterior tibial vein involvement might be due to the fact that these vessels do not drain large venous lakes as do the posterior tibials from the calf muscle group. Frykholm has proposed that collapse of veins with contiguity of vein walls is a causative factor in thrombosis of the deep leg veins in bedridden patients. The anterior tibial vessels are protected from such pressure by their anatomical position.

In 3 cases the tenderness shifted from the calf to appear in the femoral canal area without involving the intervening popliteal area. These cases may represent the syndrome described by Homans in which a thrombus originating in the leg later attaches in the femoral region or higher and unless the vein wall between the two areas is involved with the thrombus there is no tenderness.

Profunda femoris involvement, frequently overlooked has been emphasized by Homans. It is elicited by grasping the biceps femoris

muscles and squeezing moderately. In none of the 12 patients of our series with profunda femoris tenderness was its presence the only sign of tenderness in the extremity. Though it is possible that such a thrombosis might exist alone, our observations to date indicate that its presence alone is rare.

Heat. We have found that a temperature difference of 3 to 4 degrees F. can be determined fairly consistently by simple palpation. Except for a few instances, in which an electrothermocouple was used, increased heat was determined by palpation and only definite temperature differences are included.

In 54 instances, or 53 per cent, there was an appreciable temperature increase in the affected limb. Increased heat was usually accompanied by tenderness (42 extremities) and swelling (42 extremities). However there were many instances of swelling without heat (38 extremities). This latter figure includes the acute phlegmasias in which the limb was actually colder. Even with these cases excluded the incidence of swelling of an extremity without heat is still fairly high (27 instances).

Pain. This symptom was present in 54 patients at rest. Many more had pain in the calf only on walking. A few described their discomfort on walking as tightness rather than pain. This symptom was noted especially in patients in whom the level of the thrombosis was high, as in the iliofemoral thromboses. These patients complained of tightness in the thigh as well as in the calf.

Color changes. The dusky color often described as a concomitant of thrombophlebitis was noted in only 4 of our cases. There were 5 extremities which were definitely redder than their mates. One of these was the case of suppurative phlebitis. In the 11 patients with phlegmasia alba dolens discussed later the limbs were pale.

scases required 60 to 70 milligrams of heparin intravenously to maintain her $1\frac{1}{2}$ hour clotting time at 2 to 3 times normal. The answer to this problem is not clear to us and can be theorized on at length.

The reports of the Swedish investigators, Crafoord and Jorpes (8) attracted our attention sufficiently so that we tried their dosage of 100 milligrams repeatedly during the day and 100 milligrams at midnight. Most of these cases fell into our prophylactic group (not included in this paper), but 1 patient with thrombophlebitis was so treated. It was found in this group that the clotting time at 2 hours was still between 2 and 3 times the normal and tapered down from this point instead of the $1\frac{1}{2}$ hour peak of the 3 hour dosage of 50 milligrams.

A later work of Bauer (6) recommended a dosage of 50 milligrams every 4 hours during the day and 100 milligrams at midnight. Such obviously good results were obtained in his series that we decided to use this method of treatment with heparin and up to the end of this series of cases had tried this regimen in 25 cases. In this group the peak of the clotting time was usually at $1\frac{1}{2}$ hours and normal again at 4 hours.

Clotting times were taken before starting heparin then in the early cases every half hour after each dose for 2 to 3 doses. It became apparent quite early that the clotting time was down to normal within from 3 to 4 hours after each injection of 50 milligrams and well within 8 hours after the 100 milligram midnight dose. This midnight dose of 100 milligrams was used merely because we wished to give Bauer's method a fair trial. It is doubtful that this 100 milligram dose adds much to the treatment. In only 1 case in our group was the clotting time elevated 8 hours after the midnight 100 milligram dose.

For the extremely ill patient with possible liver damage one might assume from our experiences with the 3 hour dosage that it would be dangerous to give such patients 50 milligrams. In these patients the 50 milligram dose produces an unpredictable clotting time peak but as shown by our studies with the 50 milligrams every 4 hours the clotting time is invariably down to normal within 3 to 4 hours.

In none of the heparin treated patients was there any serious hemorrhage. This series is hardly large enough to base a final impression on but the results are encouraging to date.

It is quite apparent that the intermittent intravenous route of giving heparin is far from ideal although empirically of value. Loewe and his co-workers perhaps have the beginning at least of a more rational and practical method of treatment with heparin in their heparin in Pitkin's menstruum (16).

We have tried this method in 7 of our patients. In 5 cases the originally recommended dose was 300 milligrams (with vasoconstrictor). In 4 of these an adequate rise in clotting time was obtained within 12 hours and it remained elevated for 12 hours. Two of these patients required supplementary intravenous heparin every 3 hours to maintain a $1\frac{1}{2}$ hour clotting time of 2 to 3 times normal until the effect of the heparin in Pitkin's menstruum became manifest.

Two patients in this group were treated with 500 milligram doses (300 mgm. with vasoconstrictor and 200 mgm. without vasoconstrictor mixed 150 mgm. plus 100 mgm. respectively in 2 portions and injected 1 into each thigh). In these cases a good response was observed within 8 hours and the clotting times remained elevated at 2 to 3 times normal for 48 hours.

Heparin is a relatively safe anticoagulant when given intravenously by intermittent doses. Although it probably detracts from the safety element somewhat, the subcutaneous route seems to be more practical. The recent studies of McCleery and Sirak with coronamid in heparin in Pitkin's menstruum to prolong the heparin effect and consequently requiring less heparin are very encouraging and may bring us to use the subcutaneous route in the majority of cases.

Dicumarol The action of dicumarol as described by Link is primarily on the liver in inhibiting its formation of prothrombin. The anticoagulant effect of dicumarol results only from the diminution in the available prothrombin usually necessary to clot formation. Its relative insolubility except in very alkaline solution limits its practical administration to the oral route. Admittedly it is a potentially

eration there was an occluding thrombus up to the level of the profunda in the former and up to the external iliac in the latter. In the latter case it is only fair to say that there was dilatation of the entire superficial venous tree of the extremity but not above the inguinal fold.

TREATMENT

It is obvious that the treatment of venous thrombosis of the lower extremities should be directed at (1) preventing propagation of an existing clot, (2) preventing embolization and (3) keeping the patient as comfortable as possible both during and after such treatment. This study is an attempt to evaluate the efficacy of anticoagulant therapy in accomplishing this purpose.

At the beginning of this study it was decided that all patients with thrombophlebitis in the University Hospitals would be treated by anticoagulants with the exception of those particularly unsuited to this form of treatment by virtue of certain contraindications, such as subacute bacterial endocarditis renal or hepatic disease purpuric diseases bleeding lesions, those preoperative cases when in the opinion of the surgeon anticoagulants were not desirable, or those postoperative cases when large bare bleeding surfaces were to be expected.

It was also decided that these patients would be treated with bed rest in moderate Trendelenburg position (the foot of the bed on 4 to 6 inch blocks) as soon as the diagnosis of thrombophlebitis was made. The only exceptions were patients with severe or acute cardiac disease patients with restricted vital capacity and those with pulmonary embolism in whom in this position pleural pain was aggravated. This method of care was prompted by the work of Bauer (5) who showed fairly conclusively that the rate of venous blood flow was increased by this position because the veins remained small and free of stasis or laking. The purpose of this procedure is to reduce to a minimum the chances of propagation of thrombi already formed and to discourage new thrombus formation further than might be done by the anticoagulants. This study was begun when the use of anticoagulants was not as well accepted as it is now and

an added safety factor was thought advisable, however small its contribution may have been for the result herein reported. It is a procedure to be recommended especially when anticoagulants are not used as put forth by Homans and others even earlier. At the beginning of the study it was also decided that no patient should receive sympathetic blocks, local or reflex heat, or other forms of therapy directed at the thrombophlebitis.

One patient received repeated sympathetic blocks for concomitant or primary peripheral arterial embolism.

Heparin. Since the original work of Murray and Mackenzie and of Crafoord and Jorpes (8) heparin has come into clinical use increasingly both as a prophylaxis against primary thrombosis and as a preventative against propagation of the thrombosis already existent. The recent work of Loewe and Richter even further suggests that heparin may aid in dissolution of the early clot.

By virtue of its negative charges, heparin combines with prothrombin thrombin fibrinogen and thrombokinas to prevent them from acting in their usual capacity as shown by Jorpes (14).

This drug was used in 54 of our patients, exclusively in 8 and with dicumarol in 46. The average period of treatment for the whole group was from 2 to 8 days. The majority of patients were treated for from 1 to 2 days.

In the first 25 cases in which heparin was used this drug was given intravenously every 3 hours. A clotting time was taken as a control prior to treatment and 1½ hours after each dose. An attempt was made to keep this 1½ hour clotting time at from 2 to 3 times the control or the patient's normal. The majority of this group required 50 milligrams of heparin intravenously every 3 hours to maintain this level of clotting time. A few patients required as much as 60 to 70 milligrams for the same effect. In 3 extremely ill patients it was found that only 20 milligrams was required for the same effect. These patients were markedly debilitated to begin with and 2 were found later at autopsy to have hepatic involvement of moderately severe degree.

On the other hand one extremely ill patient with carcinoma of the ovary and pelvic ab-

for an occasional microscopic or transient gross hematuria.

Duration of treatment The average duration of treatment (prothrombin time of 2 times normal or above) was 14 days. In most cases the period of treatment was between 10 and 19 days.

The patients with pulmonary embolism were treated for the longest period. These comprised the group receiving between 14 and 21 days of dicumarol treatment.

Of the patients inadequately treated (only 3 to 5 days of therapy or with a prothrombin ratio not continuously between 2 and 3) only 1 died of pulmonary embolism.

We attempted to treat our patients without embolism for a period of 14 days and those with embolism for 21 days. Those without embolism were ambulated with ace bandage support as soon as all signs and symptoms were negative (usually by the seventh day) and kept under treatment until the total period of therapy was 14 days. The patients with pulmonary embolism were kept in bed for at least 10 and in most cases 14 days and kept under treatment for a total period of 21 days.

Bed rest As mentioned before, bed rest was in moderate Trendelenburg position for all patients who could tolerate it. The average length of stay in bed after the onset of the phlebitis or discovery of it was 10.5 days. Most of the patients were kept in bed for 10 days or less. It is extremely difficult to decide on the proper period of bed rest. One patient experienced a nonfatal pulmonary embolism after being in bed only 4 days. Still another was allowed up only after 18 days of therapy and 2 days after being up with a normal prothrombin time developed a pulmonary embolism.

Femoral vein ligation Ligation of the common femoral vein was performed in 8 patients in this series for various reasons as shown in Table I. In view of the arguments concerning the possibility of involvement of the profunda vein, the incidence of undiagnosed bilateral involvement, and the anatomical points brought out by Edward Edwards (10) in his recent study, we perform bilateral ligations of the common femoral. In 1 patient with a

TABLE I—FEMORAL VEIN LIGATIONS

8. W. B.	84	Repeated pulmonary embolism after two courses of dicumarol. Demonstrable phlebitis only on last attack of pulmonary embolism

phlegmonous phlebitis of the saphenous parva and deep vein involvement unilateral ligation only was done. In all, a total of 15 ligations were carried out in the 8 patients.

TYPES OF CASES

By way of interest we have divided our cases into bland and inflammatory types. Under bland thrombosis we included those without noticeable temperature change in the extremity and usually with less evidence of inflammation such as pain, tenderness or redness. The so called cases of phlebothrombosis would fall into this group, however it is admitted that according to the criteria set up at the beginning for including cases in this study we perhaps have possibly excluded some cases of so called phlebothrombosis. Thirty seven of the patients fell into this group.

Under inflammatory thrombosis we included all the rest of the patients who of course had evidences of inflammation such as noticeable temperature elevation of the extremity, pain, tenderness and in some instances color changes. Swelling is considered by us as a sign of venous obstruction for the most part although accompanying lymphangitis and local tissue reaction probably play a role in many of these cases. There were 54 cases in this group.

Acute iliofemoral thrombosis The sudden swelling of an entire lower extremity is an entity often described and probably represents the sudden involvement by a thrombus of the critical level of venous drainage just proximal

dangerous drug when its action depends on the irregularities of intestinal absorption and a special effect on the liver's prothrombin production. For these reasons one must be prepared to follow prothrombin times regularly and to combat the possible results of occasional unpredictable prothrombin depletion that may result before attempting the use of this drug as outlined below.

This anticoagulant was used in 77 of our cases. The method of dosage described by Yahr and associates and by Barker and associates was followed in essence. We gave the average patient 300 milligrams of dicumarol the first day (100 mgm. per 50 pounds of body weight) 300 milligrams the second day (two-thirds of the initial dose) and 100 milligrams on the third day (one-third the initial dose) provided the prothrombin ratio (control patient) was not 1.5 or higher. Our second day dosage was divided into 100 milligram morning and evening doses which allowed a little longer spread of our therapeutic level of prothrombin ratio from the initial dosages. This latter factor came into more importance in the prophylactic group in which a simple postoperative dosage like this (300 mgm. 100 mgm. + 100 mgm. 100 mgm.) gave a prothrombin time of 2 to 3 times the normal for 5 to 6 days without further dosage in most cases.

This divided second day dosage allowed us to stop at 400 milligrams in patients who proved to react with a significantly increased prothrombin time (1.5 times normal or more) by 24 hours after the first dose.

It took an average of 2.5 days for the prothrombin times of these patients to come to 1.5 times the normal or higher. The majority of the cases came into this range of prothrombin time within 2 days. The day after the first dose was counted as the first day. In other words a prothrombin ratio of 1.5 or higher was obtained in most patients in from 24 to 36 hours.

In the early part of our experience with dicumarol we noticed some instances of bleeding from the mucous membranes, wounds, kidneys, etc. During this time we were keeping our prothrombin ratios between 4 and 5 times the normal. As can be expected by the

curves of Quick the prothrombin time shot to extremely high levels and in some instances the plasma could not be made to clot. In these cases vitamin K in doses of 72 milligrams intravenously was given and usually the prothrombin time returned to reasonable levels within 10 to 12 hours and on repeating this dose (if necessary) in another 10 to 12 hours, the prothrombin time would be normal. We found also that whole blood transfusions would bring the prothrombin time down, but the longest effect we were able to demonstrate was 9½ hours, after which time the prothrombin time gradually returned to a high level. The higher the prothrombin time, the more blood it took to bring the prothrombin time back to normal. Fresh blood was much more potent in this effect than blood 24 hours old or older.

In a few cases secondary operative procedures, such as drainage of subphrenic abscesses, were found necessary after patients had been dicumarolized. In these cases, if the prothrombin time was only between 2 and 3 times the normal, it usually sufficed to give the patient one fresh whole blood transfusion 2 to 3 hours prior to surgery and the prothrombin time was close to normal at the time of the procedure and remained so for 8 to 9 hours and then rose again. It is only fair to mention that in 1 patient being treated prophylactically and prepared as outlined subphrenic exploration was attended by a good deal of bleeding and the patient required another transfusion before bleeding was controlled.

We might cite the case of 1 patient with an old malleolar fracture requiring surgery treated for thrombophlebitis preoperatively with dicumarol until 1 week after disappearance of signs and symptoms, at which point her prothrombin time was 2.5 times the normal. She was given 128.0 milligrams of vitamin K intravenously the night before surgery and a fresh blood transfusion a few hours before surgery and went to surgery with a normal prothrombin time. Her postoperative course was uneventful.

Keeping the prothrombin ratio between 2 and 3 times the normal rather than previous higher levels, the incidence of significant bleeding all but disappeared in this series, save

for an occasional microscopic or transient gross hematuria.

Duration of treatment The average duration of treatment (prothrombin time of 2 times normal or above) was 14 days. In most cases the period of treatment was between 10 and 19 days.

The patients with pulmonary embolism were treated for the longest period. These comprised the group receiving between 14 and 21 days of dicumarol treatment.

Of the patients inadequately treated (only 3 to 5 days of therapy or with a prothrombin ratio not continuously between 2 and 3) only 1 died of pulmonary embolism.

We attempted to treat our patients without embolism for a period of 14 days and those with embolism for 21 days. Those without embolism were ambulated with ace bandage support as soon as all signs and symptoms were negative (usually by the seventh day) and kept under treatment until the total period of therapy was 14 days. The patients with pulmonary embolism were kept in bed for at least 10 and in most cases 14 days and kept under treatment for a total period of 21 days.

Bed rest As mentioned before bed rest was in moderate Trendelenburg position for all patients who could tolerate it. The average length of stay in bed after the onset of the phlebitis or discovery of it was 10.5 days. Most of the patients were kept in bed for 10 days or less. It is extremely difficult to decide on the proper period of bed rest. One patient experienced a nonfatal pulmonary embolism after being in bed only 4 days. Still another was allowed up only after 18 days of therapy and 2 days after being up with a normal prothrombin time developed a pulmonary embolism.

Femoral vein ligation Ligation of the common femoral vein was performed in 8 patients in this series for various reasons as shown in Table I. In view of the arguments concerning the possibility of involvement of the profunda vein the incidence of undiagnosed bilateral involvement and the anatomical points brought out by Edward Edwards (10) in his recent study we perform bilateral ligations of the common femoral. phlegmonous phlebitis of the saphenous parva and deep vein involvement unilateral ligation only was done. In all, a total of 15 ligations were carried out in the 8 patients.

TYPES OF CASES

By way of interest we have divided our cases into bland and inflammatory types. Under bland thrombosis we included those without noticeable temperature change in the extremity and usually with less evidence of inflammation such as pain tenderness or redness. The so called cases of phlebothrombosis would fall into this group however, it is admitted that according to the criteria set up at the beginning for including cases in this study we perforce have possibly excluded some cases of so called phlebothrombosis. Thirty seven of the patients fell into this group.

Under inflammatory thrombosis we included all the rest of the patients who of course had evidences of inflammation such as noticeable temperature elevation of the extremity pain tenderness and in some instances color changes. Swelling is considered by us as a sign of venous obstruction for the most part, although accompanying lymphangitis and local tissue reaction probably play a role in many of these cases. There were 54 cases in this group.

Acute iliofemoral thrombosis The sudden swelling of an entire lower extremity is an entity often described and probably represents the sudden involvement by a thrombus of the critical level of venous drainage just proximal

Fig. 5. Mechanism of acute iliofemoral thrombosis.

to the profunda femoris vein. At this level the profunda femoris, the lateral and medial circumflex, and a little higher the long saphenous enter the femoral vein (Fig. 5). The tail of such a thrombus and later the thrombus itself extend well into the external iliac vein, thus the term iliofemoral thrombosis. One can readily see the extent of obstruction by such a thrombus. This sudden swelling is frequently accompanied by pain and a sense of tightness in the extremity. These limbs may be warmer or cooler, dusker or paler, and the arterial pulses may be the same or less than in the opposite limb. In our series, there were 23 extremities in this category. Three of these were in patients giving a history of old iliofemoral thrombosis with a superimposed acute process.

The so called phlegmasia alba dolens of a cold white, swollen but not always painful extremity was seen in 11 instances. There was surprisingly little incidence of pain and almost no incidence of tenderness in these. Nine of these patients were in bed at the time of onset. In the 2 patients who were ambulatory at the time of onset there was appreciable

pain. The presence of swelling may well have accounted for the failure to elicit tenderness.

Superficial thrombophlebitis. During the course of this study 5 postoperative cases of superficial thrombophlebitis were seen and treated with anticoagulants. Two cases were associated with deep thrombophlebitis. Two patients suffered pulmonary embolism calling attention to an otherwise unrecognized thrombophlebitis. Two developed while the patients were being treated for deep thrombophlebitis. All of these patients went through the natural course of the disease unaltered.

Pulmonary embolism. There were 27 patients in this series who had pulmonary embolism. These represent 29 per cent of the entire group. This figure is a little less than the 33 per cent found for untreated cases in a similar group by Welch and Faxon and by Allen (1).

In 11 patients pulmonary embolism was the first indication of the presence of thrombosis in the veins of the lower extremities. In 3 of the patients mentioned symptoms of deep vein thrombosis did not appear until several days after the embolism. In another 10 patients the thrombophlebitis and pulmonary embolism were noted on the same day. This means that 21 or 78 per cent, of these patients already had a pulmonary embolism by the time treatment could be begun.

It is interesting to note that 13 of the patients having pulmonary embolism were those with a supposedly bland type of thrombosis and 14 were in the group of those with an inflammatory process. This result seems contrary to the common belief that the bland

process leads to pulmonary embolism more often than the inflammatory process. We do not mean to leave this impression. An autopsy study such as Hunter's could very well show such a predominance of embolus resulting from the bland process for it includes patients who had thrombosis in the lower extremities without signs. Unfortunately we were not able to secure complete autopsies including leg dissections of fatalities in our hospital during the same period as our study. It is also to be argued that patients with nonfatal pulmonary embolism and without clinical evidence of thrombosis would not fall into a series like ours or an autopsy analysis. Therefore it is probably true that pulmonary embolism is more common with bland processes than with the inflammatory ones.

Six patients developed pulmonary embolism while actually on anticoagulant therapy. They cannot all be considered to have had adequate treatment however. This number includes a patient who was adequately treated for 18 days with anticoagulants. Two days after her prothrombin time had returned to normal while up and around she developed a small nonfatal embolism. After 11 more days of anticoagulant treatment she had no further trouble. This patient and one other who died were the only 2 patients who developed an embolism while treatment supposedly was adequate. The 4 remaining patients had pulmonary embolism on the first or second day after treatment was begun and so in a sense were not adequately treated. These 4 patients added to the 21 who had pulmonary embolism to begin with make 25 or 92 per cent of this group who had pulmonary embolism before anticoagulant treatment could become effective.

There were 5 deaths in our series. In only 1 can we consider pulmonary embolism as the primary cause. All of these patients were seriously ill and except for the 1 fatality mentioned, slowly succumbed to diseases other than pulmonary embolism. Three of these patients however were found to have pulmonary emboli present at autopsy but these were not thought to be the cause of death. For the evaluation of the reader a summary of the fatal cases follows.

Patient	Hospital No.	Treatment	Autopsy findings
N. B.	781977	Adquate anticoagulants	Massive pulmonary embolism; carcinoma of pancreas
J. H. K.	77 545	Inadequate heparin therapy stopped 5 d. prior to death	Far advanced ulcerative colitis with toxication; incidental pulmonary embolus
J. L. L.	751306	Bilateral femoral ligation preoperatively	Tension pneumothorax; incidental pulmonary embolus
A. M.	770417	Inadequate heparin therapy stopped 4 days prior to death	Carcinoma of pancreas with generalized metastases and incidental pulmonary embolus
S. A. K.	777476	Inadequate heparin therapy stopped 5 days prior to death	Far advanced biliary cirrhosis of the liver with external biliary fistulas

According to the data presented by Welch and Faxon about 30 per cent of the patients who have one pulmonary embolus from a thrombophlebitis will have another. They also indicate that about 25 per cent of the group of patients with one embolism will have a fatal embolism. In our series there were only 2 secondary pulmonary emboli and neither of these proved fatal.

In 19 of our cases there were x ray findings characteristic of pulmonary embolism. As can be seen by Table III most of the emboli produced x ray evidence on the right side and showed a preference for the lower lobes. This has been observed and commented on by Roesseler, Allen (2) and others. In some cases clinical evidence of pulmonary infarct was present in the lower lobes but was not recognized on the ordinary chest film because of interference by the diaphragm or heart shadows. In such cases roentgenograms in the lateral projection or with overpenetration are indicated in order to substantiate the diagnosis made.

TABLE III — LOBES INVOLVED IN PULMONARY EMBOLISM AS PROVED BY X RAY EXAMINATION

TABLE IV—ASSOCIATED FINDINGS WITH PULMONARY EMBOLISM IN THROMBOPHLEBITIS

	No. cases	Per cent
Blind process	14	31.8
Inflammatory process	13	48
Signs of thrombosis 5 to 7 days after embolism	3	1.1
Chest pain	9	70
Hemoptysis	13	33.8
X-ray findings	19	78
No x-ray findings	8	30
After surgery	5	37.5

Chest pain and hemoptysis It can be seen from Table IV that a good portion (70 per cent) of the patients had chest pain and hemoptysis. Chest pain was the most common symptom. A few patients had upper abdominal pain and a few had shoulder-strap pain at the onset of the embolism. Hemoptysis began usually within the first 24 hours after the embolism. An occasional patient did not cough up bloody sputum for several days and others had cough without sputum and some neither cough nor sputum.

Hemorrhagic manifestations It can be seen from Table V that except for patient A K all of the patients in this series who had hemorrhagic manifestations were those on dicumarol and with a prothrombin ratio of 4 or over. These cases prompted us to lower our period of treatment with dicumarol. In patients in the latter half of our series and to date, we have endeavored to keep the prothrombin ratio below 4 and preferably between 2 and 3. After this change in our form of treatment we noted a marked decrease in hemorrhagic manifestations with only an occasional transient hematuria or hemorrhagic skin lesion.

Hematuria Except for patient S R. upon whom a posttransurethral prostatectomy was performed, the urinary bleeding was not a source of concern in this group even though grossly visible in 8 cases. In all except patients S R. and H M. no change was made in the treatment and no special measures were taken to stop the bleeding. In all of these latter instances hematuria cleared up sponta-

neously within 3 days. Within 24 hours after disappearance of gross blood and in most instances sooner no microscopic evidence of blood could be found in the urine. This observation was checked by examination of separate urine specimens every 4 hours after the onset of gross hematuria. At first the patients with microscopic hematuria were checked only daily and as soon as the findings were negative examination was made only every 2 days. All of our patients had a routine urinalysis every other day. In no instance was microscopic hematuria reported prior to a pink or red urine being observed grossly. These findings have been noted in our prophylactic series also and suggest that dicumarol therapy might in some way at least be responsible for one or more small renal arteriolar or even capillary accidents from which recovery is rather rapid even when the patient is continued on the treatment. We have observed that some other patients treated with dicumarol had multiple episodes of transient hematuria.

Skin manifestations Peculiar hemorrhagic skin lesions in our patients treated with dicumarol were observed. These lesions were accompanied by a burning pain and extreme tenderness. We have seen 4 lesions (3 appearing in this series as shown in Table V) which suggested a resulting necrosis but all healed spontaneously within 10 days. Here again as in the transient hematuria, one might easily postulate some small arteriolar or capillary damage somehow related to dicumarol therapy.

No other skin lesions have been noted in our dicumarol treated patients suggestive of sensitivity or toxicity attributable to dicumarol.

PRIMARY CONDITION

To correlate the incidence of thrombophlebitis with various other conditions, an analysis of the primary diagnoses for which the patients were in the hospital was made. Other associated factors such as operations and in some cases other concomitant diseases were analyzed.

Thrombophlebitis In 9 patients or 10 per cent deep thrombophlebitis was the primary disease. A careful historical and physical re-

view of systems revealed no other significant concomitant disease. On the other hand Miller and Rogers reported a primary diagnosis of thrombophlebitis in 30 per cent of their patients a series similar to ours in numbers at least.

Cancer The high incidence of thrombophlebitis in patients with cancer has long been noted (19) and is seen in our study also. The reason for this is not yet fully apparent. In patients with thrombophlebitis one should always suspect and look for a neoplastic process when there is no apparent causative factor for the thrombosis. In 1 of our cases it was not until postmortem examination that a carcinoma of the pancreas was found.

Cancer was a concomitant or primary disease in 38 of our patients. Of these 14 had not been operated upon. The relatively higher

incidence of thrombophlebitis in postoperative cancer patients as compared with noncancer patients is shown in Table VII.

The comparatively high number of cases of gastrointestinal, gynecological, and genitourinary cancer in this series (Table VI) is due to the fact that our hospital receives an inordinate number of cases of gastrointestinal cancer and gynecological and genitourinary cancer compared with other institutions.

Pregnancy Two patients in this series were pregnant when thrombophlebitis developed. One was in the middle of the third trimester and the other in the first trimester. Both patients were given a full course of dicumarol under our plan and reacted favorably. One was given a second prophylactic course beginning on the day of delivery and had no adverse effects. The other was delivered and followed without dicumarol prophylaxis and her progress also was good.

Post partum Two other patients were noted to have thrombophlebitis within the

first 10 days post partum and were given a course of dicumarol by our plan. In both cases progress was satisfactory. In no case was nursing of the young allowed during the mother's dicumarol treatment because of the possible deleterious effect on the infant. This is still a controversial point and so a conservative attitude was adopted by our obstetric and pediatric staffs.

These results and the observations on 2 patients who had normal menses during treatment with dicumarol (Table V) would lead us to think that the uterus is little affected by dicumarol as used here. Our observations certainly are in accord with the fine work of Barnes and his associates.

Postoperative cases Again, the predominance not only of gastrointestinal and gynecological cases but also of fractured hips is noted in this group. The predominance of gastrointestinal cases is probably due to the disproportionate frequency of these operations here due to the special interest of our staff in these conditions. These 38 postoperative cases represent 41.0 per cent of the entire series.

All other conditions Of all the fractures of the lower extremity seen in our hospital during the period of this study only 4 were treated with traction alone. None of these patients developed evidence of thrombophlebitis of the lower extremities.

The relative absence of surgery in our cases involving the hip or lower extremity would seem to indict surgery but this would be unfair. In most of our cases of fracture treatment was by internal fixation casts, or both. Patients with fractures of the lower extremity (the majority of the hip) admitted usually a week or more after their fracture and often for secondary reparative surgery represent the great bulk of our operative fracture cases. These facts taken into due consideration would account for the figures as they stand. During the period of our study there were 60 hip operations for fracture in our hospital. In 4 or 6.6 per cent of these thrombophlebitis developed (Table VII).

The early part of our study was contemporary with the great poliomyelitis epidemic of 1946. Seven patients with poliomyelitis

were examined for the presence of thrombophlebitis. In all the patients examined with the signs and symptoms of poliomyelitis it was easy to identify those with thrombophlebitis. Only 3 cases however are included in this series. In these cases the thrombophlebitis occurred in the postinflammatory state of the poliomyelitis when the signs of swelling heat in the extremity and elevation of vital signs should not have been caused by the poliomyelitis. Muscle pain and tenderness while present could not be used as evidence as they are common to both diseases.

That we may have missed some cases of thrombophlebitis in those seen in the acute stage of poliomyelitis and that some or all of the cases we included may have been exacerbations of poliomyelitis is not denied.

The incidence of cardiac disease as recorded is low because only those patients without other disease are included. A great number of our patients had cardiac disease along with their other difficulties but no special effort was made to correlate this finding as a separate entity.

As has been noted by Dennis, the incidence of thrombophlebitis in ulcerative colitis is about 30 per cent. In full cognizance of this fact all patients with ulcerative colitis operated upon in our hospital for ileostomy are given prophylactic anticoagulants. As a result none of our patients with ulcerative colitis having ileostomy operations has developed thrombophlebitis since this prophylaxis was instituted.

RESULTS

All of our results must be considered from the standpoint of our entire method of treatment which includes anticoagulants as the main instrument. Without anticoagulants the bed rest in Trendelenburg position plays a large role, in our opinion in getting our patients well and preventing pulmonary embolism.

As has been stated, there were no cases of secondary fatal pulmonary embolism and only 2 cases of pulmonary embolism after or during supposedly adequate treatment. There was only 1 fatality in the entire group supposedly adequately treated with anticoagulants.

Following is a résumé of the average number of days before return to normal or relief from vital signs, 4.8 days (majority 3 to 4 days), pain 4.0 days (majority 3 to 4 days), tenderness 8.0 days (majority 5 to 8 days), swelling 2.0 days (majority 1 to 2 days).

Actually our 27 patients with pulmonary embolism represent 20 per cent of the entire series, a little less than the 33 per cent incidence of pulmonary embolism usually found in untreated thrombophlebitis.

CONCLUSIONS

Our observations lead us to believe that the most indicative signs in venous thrombosis of the lower extremities are swelling, tenderness, temperature change, and pain. The high incidence of deep calf tenderness in our series leads us to rely more on this sign than on the presence of tenderness to calf squeeze or a positive Homans' sign. However we consider calf squeeze tenderness and a positive Homans' sign as necessary adjuncts in making a diagnosis but when present alone they are probably not as dependable as deep calf tenderness. Color changes, dilatation of superficial veins, and increase in vital signs are helpful when present but probably not of great significance in making a diagnosis of deep vein thrombosis due to the infrequency of their occurrence.

The use of anticoagulants in the treatment of our patients has been very encouraging to date and has reduced the incidence of secondary embolism from an expected 30 per cent to 2.17 per cent. It has reduced the rate of secondary fatal embolism from an expected 25 per cent to zero. The use of anticoagulant treatment has not significantly affected the over all incidence of primary pulmonary embolism. This cannot be considered as a deficiency of the treatment because most of our patients with pulmonary embolism had already had the embolism at the time of the diagnosis of thrombophlebitis. It would seem to emphasize the value of prophylaxis.

We are impressed with the high incidence of thrombophlebitis in patients with cancer and believe that these patients should have prophylactic postoperative use of anticoagulants. Such prophylaxis seems to be indicated in patients having major gastrointestinal opera-

tions, hysterectomies, and hip fixations, especially those with cancer.

We believe the use of anticoagulants with bed rest in mild Trendelenburg position is a satisfactory way of treating thrombophlebitis. Ligations are also indicated in some cases. We do not believe sympathetic blocks necessary for the treatment of acute thrombophlebitis of the lower extremity.

For the most part, the use of dicumarol keeping the patient's prothrombin time at 2 to 3 times normal for 14 days with the patient ambulatory for at least the last 7 days is probably an adequate course of therapy for deep vein thrombophlebitis.

It appears that the use of heparin in 50 milligram doses intravenously every 4 hours omitting the 4:00 a. m. dose may well be an adequate form of treatment. Our experience with this method is still too limited to draw any just conclusions as yet. This is also true of our small experience with heparin in Pitkin's menstruum.

It is likely that the answer to the question of thrombophlebitis does not lie in perfecting the anticoagulants and their administration but rather in the fundamental cause of abnormal blood clotting.

SUMMARY

1. Ninety-two cases representing 105 extremities with deep thrombophlebitis of the lower extremities are presented.

2. The incidence of diagnostic signs and symptoms are recorded and evaluated.

3. A method of treatment with heparin and dicumarol used in 84 of the cases is presented.

4. The cases of 8 patients who were treated with ligation are also presented.

5. Twenty-three cases of acute iliofemoral thrombosis including 11 cases of so called phlegmasia alba dolens are presented.

6. The incidence of pulmonary embolism before and after anticoagulants is discussed.

7. The complications of anticoagulant therapy are presented and discussed.

THE SURGICAL MANAGEMENT OF ULCERATIVE COLITIS

G GAVIN MILLER, M.D., F.R.C.S (C) CHARLES B RIPSTEIN M.D., F.R.C.S (C) and
EDWARD J TABAH M.D., Montreal Quebec

IN recent years the therapy of ulcerative colitis has undergone a radical change. Advances in preoperative preparation and in postoperative care have made surgery safer. As a result more patients are being treated by surgical measures and more radical operative procedures are being recommended. In the past the aim of treatment has been to put the diseased bowel at rest by diverting the fecal stream with an ileostomy. Although this form of management gives good results in some cases it is now realized that when extensive pathological changes have occurred in the bowel wall it never reverts to normal. Continuity of the intestinal stream can seldom be restored without grave danger of recurrence. The diseased bowel may also act as a focus of infection which prevents complete restoration to health. Furthermore the possibility of polyposis and malignant degeneration always exists. Consequently as surgery has become safer there has been an increasing tendency to follow initial ileostomy with resection of the colon in one or more stages (9). The results of colectomy have been relatively good. Cattell (2) states that three quarters of the patients thus treated have remained well and have been able to resume their former occupations. Others have had a similar experience. The purpose of this paper is to present the technique of surgical management which we have adopted at the Royal Victoria Hospital.

SELECTION OF CASES FOR OPERATION

Ulcerative colitis is a disease of variable severity and relatively few cases demand surgical treatment. In most clinics 20 to 25 per cent of all patients come to operation. It must be remembered that surgery is only indicated in intractable or complicated cases and as a rule anyone that undergoes operation represents a medical failure. For this

reason comparison of the results and mortality of medically and surgically treated groups is unfair and gives little indication of the value of any procedure.

Clinically cases of ulcerative colitis can be divided into three groups.

Group I The acute fulminating type with extreme toxemia, massive hemorrhage, and rapidly downhill course. The results of treatment are poorest in this group. Surgery offers little prospect of alleviation and carries a prohibitive mortality. Patients so afflicted should be treated medically with antibiotics and blood transfusion. Crohn (6) has stated that streptomycin is sometimes of value. The medical ileostomy with the Miller Abbott tube may also be useful (11). If operation is contemplated it must be performed early before the patient is in a moribund condition.

Group II Chronic cases of moderate severity characterized by remissions and exacerbations. Most of the surgical patients fall into this group and the indications for operation may be classified as follows:

1 *Intractable cases* These follow a downhill course with increasingly frequent and severe exacerbations which cannot be controlled by medical therapy. Episodes of diarrhea and bleeding recur and weight loss, anemia and liver damage become more marked. In the past such patients have been subjected to operation as a last hope. With improved preoperative preparation, and a feasible means of controlling the ileostomy, earlier surgical intervention is indicated.

2 *Complicated cases*

a *Perforation* This complication occurs in about 1 per cent of patients. It is especially likely in acute cases or chronic cases with stricture formation. A virulent form of peritonitis results which is almost universally fatal. In most instances there are warning signs of impending perforation and these must be regarded as an urgent indication for surgery.

From the Department of Surgery, Royal Victoria Hospital and McGill University, Montreal.

b Stricture formation Narrowing of the bowel lumen due to scarring occurs in 5 per cent of cases of ulcerative colitis. The commonest site is in the rectum. As a rule the stenosis is not severe enough to cause complete intestinal obstruction. The lesion is irreversible and demands surgical treatment.

c Polypsosis This represents the most common complication in chronic cases, the incidence being 10 per cent. The lesions are pseudopolyps, representing hyperplastic islands of epithelium between the ulcerated areas. Polypsosis constitutes an indication for surgery because of the danger of recurring hemorrhage and malignant degeneration.

d Carcinoma. There has been some controversy about the frequency of malignant change in chronic ulcerative colitis. Lynn found an average incidence of 2 per cent in a large series of cases. Cattell and Boehme (4) feel that the true prevalence is greater than the reported figures. It appears likely that with more patients surviving longer periods because of improved medical therapy the incidence of carcinoma may become higher. The tumors that develop in these patients are extremely malignant and metastasize rapidly. The slightest suspicion of carcinoma demands early radical surgery.

e Massive hemorrhage Bleeding is fairly common during exacerbations of the disease but massive melena is relatively rare. When it does occur it constitutes a very serious complication and carries a high mortality. If conservative treatment does not control hemorrhage within 48 hours, surgical intervention is indicated.

f Abscess and fistula formation These are local complications which arise as a result of infection and ulceration in the colon or rectum. Persistent fistulas result from opening of abscesses into the surrounding tissues or neighboring organs. The only effective treatment is diversion of the fecal stream and subsequent excision of the diseased bowel. If the rectum is not removed symptoms persist despite ileostomy and colectomy.

g. Segmental ulcerative colitis (7) This represents a rare form of the disease in which the lesions are limited to an isolated segment of the colon. Such cases can be cured by resection

of the involved bowel. This should be done early to avoid further extension of the pathological process.

Group III Many patients have a very mild type of disease in which pathological changes are not severe and symptoms constitute an inconvenience rather than a disability. They rarely develop complications and the mortality is low. Such cases respond well to medical and psychiatric therapy and do not require surgical intervention unless complications or severe exacerbations ensue.

PREOPERATIVE PREPARATION

The most frequent cause of morbidity in the surgery of ulcerative colitis has been the failure to prepare these patients adequately for operation. The local lesion in the bowel is invariably accompanied by nutritional deficiencies, anemia, sepsis, and toxemia. These are usually of long duration and their correction requires an intensive preoperative regimen. The chief aims are to control symptoms, to restore nutrition and to combat infection. In most cases the patient can be returned to excellent condition and the risk of operation is greatly reduced.

Control of symptoms Abdominal cramps and diarrhea are usually the outstanding complaints. These can be alleviated to some extent by a bland low residue diet, absorbent powders such as bismuth and kaolin and sedative drugs. The psychic aspect of these patients should not be neglected. It is useless to attempt psychotherapy as a primary means of treatment when severe organic changes have occurred in the bowel. However symptomatic relief may often be obtained and the patient can be prepared for the inevitable mental disturbance of an operation and a subsequent ileostomy.

Nutritional deficiencies Hypoproteinemia is common in these patients due to inadequate intake, impaired absorption and excessive loss in the bowel. It is important to realize that the plasma protein level is maintained at the expense of the tissues and a marked degree of deficiency may occur with little change in the blood. It is safe to assume that all patients with chronic ulcerative colitis are in an actual or potential state of protein deficiency. The

Fig. 1. Barium enema. Extensive ulcerative colitis involving the entire large bowel.

Fig. 2. Barium enema. Ulcerative colitis with polyposis involving the entire colon.

best form of treatment is a high protein diet. The requirements may be 200 to 300 grams a day and to reach this the diet must be supplemented by concentrated feedings. If a sufficient oral intake cannot be achieved the requirements are met by tube feedings through a nasal catheter or by the intravenous use of whole blood, concentrated plasma and protein hydrolysates. This therapy must be continued until the deficiency is fully corrected. Restoration of a positive nitrogen balance often gives rise to dramatic improvement in the patient's condition.

Vitamin deficiencies are also common. Administration of the B complex and vitamin C in adequate dosage is necessary to restore the nutritional status to normal. There is no indication that lack of any specific vitamin plays a part in the etiology or progress of the disease. The deficiencies that exist are part of the general picture of malnutrition. Liver damage of varying severity is not unusual (5). This may give rise to a prolonged prothrombin time which aggravates the bleeding tendency.

Vitamin K must be administered in sufficient dosage to overcome this.

Anemia is a constant finding in severe cases due to blood loss, malnutrition, liver damage and perhaps to toxic depression of the bone marrow. Beneficial effects have been reported from the use of liver extract and this should be given as part of the preoperative preparation. There is no satisfactory substitute for whole blood as a means of restoring the hemoglobin to normal levels. Repeated small transfusions seem to be utilized better than occasional large ones. Blood is a good source of protein and also supplies certain nonspecific factors which appear to be of benefit in the chronically ill patient.

Because of diarrhea the water and electrolyte balance may be disturbed. This factor must be corrected in the preoperative period by careful administration of physiological saline and glucose saline.

Control of infection. Many papers have appeared in the literature reporting good results from the use of chemotherapeutic agents in

its removal immediately decreases toxic absorption with its consequent systemic effect. Besides removing the toxic focus of the right colon this procedure saves at least one stage in total colectomy. We also feel that such a plan of operation avoids certain complications which occur frequently with other methods. In reviewing the cases of ulcerative colitis treated at the Royal Victoria Hospital in the last 10 years we have noted the following tendencies:

1. In a large percentage of cases simple ileostomy fails to relieve symptoms and it is difficult to build the patient up sufficiently for a subsequent colectomy. Following later resection of the right colon many of these patients showed improvement.

2. Any procedure which involves anastomosis of the diseased bowel is extremely hazardous. In 6 cases in which colectomy was done with ileosigmoidostomy the mortality was 50 per cent. In all cases death was due to peritonitis.

The operation is carried out under spinal anesthesia. A long right rectus incision is made and the ileum is divided 10 to 12 centimeters from the ileocecal valve in an area free from disease. The proximal end of the bowel is brought out through a stab wound 6 centimeters below the umbilicus and 3 centimeters to the right of the midline. This is the optimum site for the use of the Koeng Rutzen bag (8). The terminal ileum and the right half of the colon are then removed in the usual fashion and the proximal end of the divided transverse colon is exteriorized through a stab wound. We feel that it is dangerous to attempt inversion of the diseased bowel and the stoma can be used for future irrigations and installation of antibiotics. Silk technique is used throughout and the incision is closed without drainage with stainless steel wire.

There is usually a remarkable improvement following this procedure. Symptoms subside and weight is rapidly regained. In some cases the benefits are so marked that it is difficult to persuade the patient to undergo another operation. Excision of the remaining bowel is definitely indicated if there has been severe rectal involvement, polyposis, stricture or anorectal fistulas. If the distal colon is not re-

moved it should be examined periodically by proctoscopic and x-ray visualization.

The second stage is carried out in 6 months after careful preoperative preparation. Through a left rectus incision the remaining colon is resected to the level of the rectosigmoid. If the patient's condition is good and the disease involves the rectum this stage may be done as a combined abdominoperineal resection. The two team technique which we have used in cancer operations enables us to perform this in a short time with little added risk. We feel that complete colectomy is usually necessary to obtain the best results. In some cases we have shortened the interval between stages with no ill effects.

POSTOPERATIVE CARE

In the immediate postoperative period the chief aims of treatment are to prevent shock, combat infection, and replace the fluid and electrolyte loss from the ileostomy stoma. Blood transfusion, intravenous saline, and the administration of penicillin and streptomycin have solved these problems to a great extent.

Later the question of ileostomy care becomes important.

At the time of operation a catheter is fixed into the projecting ileum with a pursestring suture. This catheter is connected to an intermittent suction device on return to the ward. As a rule this measure protects the skin for 48 to 72 hours and then the catheter becomes loose. Skin excoriation is difficult to prevent but with careful nursing and frequent dressings it can be kept to a minimum and has not constituted an insurmountable problem in any case. Many substances have been recommended to prevent skin digestion: Aluminum powder, kaolin, ground beef, and Lassar's paste have all been used in our series. No one has proved to be of outstanding value.

Seven to 10 days after operation an adjustable type of ileostomy bag can be used and in 2 months when the stoma has shrunk the patient can be fitted with a made-to-measure Koeng Rutzen bag. This apparatus has revolutionized the care of the ileostomy and it is now safe to say that a properly made ileostomy is no more troublesome than a colostomy. As time passes the ileal contents become more

Fig. 3. Diagram of incision used in two-stage colectomy. A, Incision for right hemicolectomy. B, site of ileostomy. C, site of exteriorized transverse colon. D, incision for second stage colectomy.

ulcerative colitis. In most of these the follow-up has been inadequate and the prevalent opinion at the moment is that no antibacterial agent is of specific value in this disease (1). This has been our own experience.

From the surgical standpoint sterilization of the bowel contents is vitally important. Even though infection may be a secondary matter it is responsible for many of the complications and deaths that result from surgical intervention. The use of sulfathalidine, streptomycin, and penicillin makes operation safer. The routine we have adopted is to give sulfathalidine for 5 to 6 days prior to operation supplemented by streptomycin orally for the last 48 hours. In the postoperative period penicillin and streptomycin are given by intramuscular injection. With this method the bacterial count of the feces is reduced to an extremely low level and there is often an improvement in the local manifestations of the disease. The dangers of peritonitis and wound infection are minimized in the postoperative period.

OPERATIVE PROCEDURE

It is almost always possible to plan an elective attack in a well prepared patient. In the past the surgical mortality has been high and two-thirds of the deaths have occurred in cases in which operation has been carried out

as an emergency (2). Emergency operations should be avoided wherever possible.

The operation of choice has usually been an initial ileostomy which is followed in 6 months by a staged resection of the colon. We feel that a permanent ileostomy is the price which must be paid for a satisfactory result. Closure of the ileostomy leads to recurrence in a large percentage of cases.

If the fecal stream is diverted and the colon left *in situ* the patient may improve symptomatically but the dangers of sepsis, hemorrhage and malignancy are still present. It seems to be well established that the only way to produce a lasting cure in most cases is by complete excision of the involved bowel.

It is not advisable to anastomose the ileum to the rectal stump because in the majority of patients the rectum and rectosigmoid are the most involved parts of the bowel and an abdominoperineal resection may be necessary to eradicate the disease.

Ravitch and Sabiston have advocated a pull through type of operation in which the ileum is brought down through the intact anal sphincter resulting in a continent anal ileostomy. This procedure offers a great deal of promise but it is still too new to assess its end results.

We have adopted the policy of performing ileostomy with right hemicolectomy as an initial procedure in ulcerative colitis. The idea began accidentally when one of us (G.G.M.) was obliged to resect the right colon because of multiple perforations in a very ill patient. The result was surprising. The patient improved dramatically, her fever subsided and she began to put on weight. The resected bowel was literally "a bag of pus." It was considered that removal of the right half of the colon as an initial procedure might eradicate a source of infection and thus enable the patient to respond more quickly. This operation has subsequently been carried out in 6 patients with no deaths, and uniformly good results. We feel that it is less radical than it appears to be at first glance and that with proper preoperative preparation it can be done with a lower mortality than simple ileostomy. The benefits are obvious. Since the right half of the colon is the absorptive part of the bowel

its removal immediately decreases toxic absorption with its consequent systemic effect. Besides removing the toxic focus of the right colon this procedure saves at least one stage in total colectomy. We also feel that such a plan of operation avoids certain complications which occur frequently with other methods. In reviewing the cases of ulcerative colitis treated at the Royal Victoria Hospital in the last 10 years we have noted the following tendencies:

1. In a large percentage of cases simple ileostomy fails to relieve symptoms and it is difficult to build the patient up sufficiently for a subsequent colectomy. Following later resection of the right colon many of these patients showed improvement.

2. Any procedure which involves anastomosis of the diseased bowel is extremely hazardous. In 6 cases in which colectomy was done with ileosigmoidostomy the mortality was 50 per cent. In all cases death was due to peritonitis.

The operation is carried out under spinal anesthesia. A long right rectus incision is made and the ileum is divided 10 to 12 centimeters from the ileocaecal valve in an area free from disease. The proximal end of the bowel is brought out through a stab wound 6 centimeters below the umbilicus and 3 centimeters to the right of the midline. This is the optimum site for the use of the Koenig Rutzen bag (8). The terminal ileum and the right half of the colon are then removed in the usual fashion and the proximal end of the divided transverse colon is exteriorized through a stab wound. We feel that it is dangerous to attempt inversion of the diseased bowel and the stoma can be used for future irrigations and instillation of antibiotics. Silk technique is used throughout and the incision is closed without drainage with stainless steel wire.

There is usually a remarkable improvement following this procedure. Symptoms subside and weight is rapidly regained. In some cases the benefits are so marked that it is difficult to persuade the patient to undergo another operation. Excision of the remaining bowel is definitely indicated if there has been severe rectal involvement, polyposis, stricture or anorectal fistulas. If the distal colon is not re-

moved it should be examined periodically by proctoscopic and x-ray visualization.

The second stage is carried out in 6 months after careful preoperative preparation. Through a left rectus incision the remaining colon is resected to the level of the rectosigmoid. If the patient's condition is good and the disease involves the rectum this stage may be done as a combined abdominoperineal resection. The two-team technique which we have used in cancer operations enables us to perform this in a short time with little added risk. We feel that complete colectomy is usually necessary to obtain the best results. In some cases we have shortened the interval between stages with no ill effects.

POSTOPERATIVE CARE

In the immediate postoperative period the chief aims of treatment are to prevent shock, combat infection, and replace the fluid and electrolyte loss from the ileostomy stoma. Blood transfusion, intravenous saline, and the administration of penicillin and streptomycin have solved these problems to a great extent.

Later the question of ileostomy care becomes important.

At the time of operation a catheter is fixed into the projecting ileum with a pursestring suture. This catheter is connected to an intermittent suction device on return to the ward. As a rule this measure protects the skin for 48 to 72 hours and then the catheter becomes loose. Skin excoriation is difficult to prevent but with careful nursing and frequent dressings it can be kept to a minimum and has not constituted an insurmountable problem in any case. Many substances have been recommended to prevent skin digestion. Aluminum powder, kaolin, ground beef, and Lassar's paste have all been used in our series. No one has proved to be of outstanding value.

Seven to 10 days after operation an adjustable type of ileostomy bag can be used and in 2 months when the stoma has shrunk the patient can be fitted with a made-to-measure Koenig Rutzen bag. This apparatus has revolutionized the care of the ileostomy and it is now safe to say that a properly made ileostomy is no more troublesome than a colostomy. As time passes the ileal contents become more

Fig. 4. Photograph of patient, Case 1, wearing the Koenig-Rutsen bag.

solid and less irritating and the patient can lead an active life.

To date we have not attempted a pull through operation to form a continent anal stoma. If such a procedure is contemplated it would appear wise to wait 6 to 8 months until the ileostomy discharge becomes relatively solid and nonirritating.

CASE REPORTS

The following case reports illustrate some of the problems involved in the surgical management of ulcerative colitis.

CASE 1. Patient R. R., male, aged 36 years, was admitted to the Royal Victoria Hospital September 25, 1946. He had been comparatively well until 5 months before admission at which time he began to have diarrhea and slight bleeding associated with his bowel movements. The melena became more severe and he required transfusion on several occasions. There was a rapid loss of weight (40 lbs.) during the next few months.

On admission he was pale, emaciated and appeared moderately ill. Investigation by barium enema and proctoscopic examination revealed an extensive ulcerative colitis with polyposis involving the entire colon (Fig. 5).

The hemoglobin was 68 per cent and the plasma protein level was 4.38 grams per cent on admission. The protein fell to 3.65 in the next week despite a high protein diet and blood transfusion. Intensive whole blood plasma and amigen therapy was then commenced and the plasma protein level rose steadily to reach a height of 6.0 grams per cent at the time of the first operation (Fig. 5). On October 18, 1946 ileostomy and right hemicolectomy were performed. Extensive disease of the whole colon, as found and the mesentery was thickened and edematous.

The postoperative course was complicated by obstruction of the ileostomy stoma which necessitated revision on November 7, 1946. Following this he began to gain in weight and strength and his plasma proteins continued to rise to reach a level of 7.19 grams per cent with a hemoglobin of 86 per cent. On November 30, 1946 a second stage colectomy was performed. The entire remaining colon and rectum were resected by a two team abdominoperineal procedure. During this operation a large pelvic abscess was opened contaminating the peritoneal cavity. The postoperative course was stormy being complicated by a low grade peritonitis due to *Bacillus coli*. This was successfully treated with streptomycin and penicillin and the patient was discharged December 18, 1946. He has remained well since that time. His ileostomy functions well and he is comfortable and active using the Koenig-Rutsen bag. He has no symptoms and his weight and general health are completely restored.

This case demonstrates several important points.

1. The state of hypoproteinemia and the massive protein intake required to overcome it.

2. The complication of low grade peritonitis which may result from perforation with local abscess or from cutting through infected mesenteric lymph nodes. This danger necessitates the use of streptomycin and penicillin in the postoperative period.

3. The short time interval between the two stages was due to the fact that carcinoma was suspected because of the pelvic mass which turned out to be an abscess.

4. The profuse ileostomy drainage in the first few postoperative days. This must be carefully measured and the fluid and electrolyte loss replaced. It has been estimated that 7 grams of sodium chloride is lost in each 1000 cubic centimeters of ileostomy drainage (Fig. 6).

CASE 2. Patient D. M., female, aged 22 years, was admitted to the Royal Victoria Hospital July 31,

Fig 5 Case 1 Response of plasma protein level to parenteral infusion

Blood	750	1000	1000	1000
Plasma	500	500	1000	500
Amigen	2000	5000	3000	2000

1946. For 3 months before admission she had noticed increasing weakness and loss of weight. About 6 weeks after the onset of these symptoms she began to have severe diarrhea with blood and mucus appearing in the stool. She was admitted to hospital in her home town and treated with penicillin, sulfadiazine and blood transfusion. This regimen did no good and she was advised to come to Montreal.

On admission the patient was pale emaciated and ill. Physical examination revealed no significant findings.

Barium enema and proctoscopic examination established the diagnosis of an extensive ulcerative colitis with polyposis. The disease involved the entire colon with the exception of the cecum. Culture of the stool, parasite search, and allergy investigation all yielded negative results.

On admission her hemoglobin was 68 per cent and her plasma protein level 3.85 grams per cent.

The patient was acutely ill and ran a spiking fever of 102 to 103 degrees. She was treated with sulfathiazine, penicillin and blood transfusions and an attempt was made to restore her nutrition. Despite these efforts her course continued downhill and on August 25, 1946 she was transferred to surgery.

She was put on intensive intravenous protein therapy with massive blood and plasma infusions. With this her plasma proteins rose to 6.08 grams per cent and her condition improved. On September 10, 1946 under spinal anesthesia ileostomy and right hemicolectomy were performed. The postoperative course was uneventful, whole blood transfusion, sulfadiazine and penicillin were continued. Her condition improved rapidly and she began to gain weight. She continued to run a low grade fever and to have discharge of blood and pus per rectum. Irrigations of sulfathiazine through the colostomy opening gave some relief and she was discharged November 24, 1946 markedly improved.

Fig 6 Case 1 Chart of intake and output in post-operative period, illustrating ileostomy loss in the first 48 hours.

The patient was readmitted June 3, 1947. She had been well in the interval and her ileostomy was controlled with the Koenig Rutzén bag. She had gained weight and her plasma protein level was 6.2 grams per cent. Laparotomy was undertaken June 11, 1947 after a preliminary course of sulfathiazine and streptomycin. A pelvic abscess was found and drained and the abdomen was closed. The postoperative course was uneventful and on October 7, 1947 the abdomen was again opened and second stage colectomy carried out leaving the rectum *in situ*. The postoperative course was smooth and the patient was discharged October 18, 1947. Since that time she has remained well.

This case represents the more acute fulminating type of disease. The improvement following right hemicolectomy was dramatic. The problem of restoring protein nutrition was again troublesome and large amounts of oral and parenteral protein were necessary to maintain nitrogen balance. It has been shown that these patients may lose as much as 25 grams of protein daily in the stools alone. The complication of peritoneal infection was again present and required intensive antibiotic therapy.

SUMMARY AND CONCLUSIONS

1. The indications for surgery in the treatment of ulcerative colitis are discussed. Op-

eration should be reserved for intractable or complicated cases and cases with segmental bowel involvement

2 Preoperative preparation is important. The aims are to restore nutrition, control infection and alleviate symptoms. Restoration of a positive nitrogen balance may be difficult and require large amounts of protein orally and parenterally

3 The initial operative procedure of choice is an ileostomy with right hemicolectomy followed in 6 months or less by resection of the remaining diseased bowel

4 The chief problems in the postoperative period are the control of infection which requires the use of streptomycin and penicillin and the replacement of fluid and electrolyte loss from the ileostomy

5 The diseased colon should be resected because of the dangers of infection, hemorrhage and malignant degeneration. It is rarely possible to re-establish intestinal continuity without recurrence of symptoms.

6 The rectum must be removed in all cases with severe rectal ulceration, stricture, polyps, or anorectal fistulas.

7 At the present time a permanent ileostomy must be accepted as the price of a good result. With the Koenig Rutzén bag an ileostomy does not constitute a great disability.

CRANIOFACIAL MORPHOLOGY IN CLEFT PALATE AND CLEFT LIP DEFORMITIES

T M GRABER, D.D.S., M.S.D. Chicago, Illinois

MAN has a rather definite idea of just what he should look like. He is liberal enough to allow certain individual differences but the basic physiognomical pattern is set. A man may have a withered arm or a club foot but facial aberrations may prove a much greater handicap as the unfortunate individual tries to take his place in society. And when this critical attitude toward facial deformities is combined with the individual's own hypersensitive psychic response the problem becomes even more complex. In congenital defects such as cleft palate and cleft lip the surgeon starts with an abnormal pattern of obscure etiology, unknown growth and development and questionable prognosis. Surgical management labors under a further handicap because in spite of the fact that therapy is instituted quite early any appraisal of the results must await nature's fullest contribution conferred by maturity. Despite refinement of surgical techniques a number of provocative questions must be answered before any definite criteria for success and failure can be established. Why do we see such wide variations in facial appearance among the cleft palate group? Are the ultimate results different for different surgical techniques and timing? Can fibrous bands of scar tissue resulting from soft tissue repair hold back growth and development? What is the developmental pattern in patients operated upon versus that in those not operated upon? These questions are the basis of the following report of a continuing study in which we have attempted to determine the differences that exist between this particular congenital deformity and the normal pattern.

Embryological study reveals clearly what happens (Fig. 1). Cleft lip results from the failure of union of the maxillary and median nasal processes. According to Sicher, tenuous

epithelial union does take place at one stage but because it is not replaced with mesodermal tissue it later gives way. Cleft palate results from a lack of fusion of the palatal processes with one another and with the nasal septum. The obscure etiology has given rise to a host of theories on the nature of cleft palate. Brophy and Logan were of the opinion that the maxilla was much broader in cleft palate patients than in normal ones and that the cleft was the result of failure of union of well developed parts (12) necessitating early osteoauranoplasty to prevent atrophy of the soft tissue and spreading of the cleft by action of the tongue and pressure of the mandible against the inclined planes of the alveoli. Others (2, 3, 4, 13, 23) have felt that there is an inherent lack of tissue and have relied on such operations as the modified Dorrance pushback techniques attempting closure by soft tissue only. Of considerable interest to the followers of either philosophy is the timetable of maxillary growth to serve as a basis for operative timing. Todd and Brash have both shown from large samplings of skeletal material that approximately five sixths of the total palatal breadth have been accomplished by the end of the 4th year in normal individuals with total width increments by the end of the 10th year (5, 28).

The present analysis of the developmental patterns and facial morphology in cleft palate is part of a serial or longitudinal survey and critical appraisal of the developing aberration. All patients are being followed and examined at regular intervals. The subjects for this investigation were 45 cleft palate patients ranging in age from 7 months to 58 years, selected at random but with some effort to include patients not operated upon as well as those operated upon. Deformities varied from simple alveolar cleft to complete bilateral lip and palate clefts. Table I shows the varying types. The method of study was primarily roentgen

From the Department of Orthodontics, Northwestern University School of Dentistry.

Fig. Embryonic processes contributing to facial development and their adult derivatives.

ographic The Broadbent Bolton cephalometer (6) was used as a means of accurately positioning the patient's head to the film and x ray tubes (Figs. 2 3 4). Plaster casts, photographs, and a series of five head plates were taken of each patient, and case histories were compiled. Three lateral plates, wide open mouth physiologic rest and occlusion and two anteroposterior plates positions of physiologic rest and occlusion were taken—or about 225 views in all. The following anthropometric landmarks and measurepoints seen in Figure 5 were used:

1. Nasion. The frontonasal suture or junction of frontal and nasal bones.
2. Sella turcica. The center of the bony crypt occupied by the hypophyseal cerebri. Roentgenographically a very constant profile outline seen in its lateral aspect.

3. Porion. This is a machine registration of the center of the external auditory meatus not necessarily corresponding to the anthropometric landmark in the skull proper but nevertheless constant.

4. Orbitale. The lowest point on the inferior bony margin of the orbit, usually as viewed in the lateral plate.

5. Gnathion. The most outward and everted point on the profile curvature of the symphysis of the mandible.

6. Gonion. The most outward and everted point on the angle formed by the junction of the ramus and body of the mandible on its posterior inferior aspect.

7. Anterior nasal spine. The spinous process of the maxilla forming the most anterior projection of the floor of the nasal cavity.

8. Pterygomaxillary fissure. An oval looped radio-lucency resulting from the fissure left by the pterygoid process of the sphenoid bone and the most posterior portion of the maxilla.

9. Pogonion. The most anterior point on the symphysis of the mandible.

10. Point A. An arbitrary [measure] point, taken at the innermost curvature from anterior nasal spine to the crest of the maxillary alveolar process, signifying the approximate juncture of the basal or supporting maxillary bone and the alveolar bone.

Alveolar cleft				
Soft palate and soft palate				

Since the introduction of the Broadbent Bolton cephalometer in 1931 numerous studies have been made on growth and development of children, normal and abnormal. Of special interest are the works of Brodie and his co-workers (9 10, 11) Broadbent (7 8) Herzberg and Holic, Mayne, Brash Thompson Toothaker Baldrige, and Downs. These to-

gether with studies made on skeletal material (16-19, 21, 22, 29) form a basis of comparison in any study of congenital or environmental

deformities. Certain criteria for determining facial characteristics have been set up based on those used by other investigators in studies

TABLE II.—NORMAL CRITERIA FOR DETERMINING CRANIOFACIAL DEVELOPMENT

Criteria	Investigator	Mean	Range	S D	Material
Nasal height	Brash	41.1% (infants)			Skulls
		41.81% (adults)			
	Brodie	3%			Normal children
	Herzberg and Holic	43.31%	1.4%	$\pm 1.6^{\circ}$	Skulls
Maxillary height	Mayne	43.05%	30.7-40.1	$\pm .40^{\circ}$	30 adults
	Mayne	41.04%	37.2-50	$\pm .08^{\circ}$	30 adults
Intermaxillary clearance	Thompson	2-3mm			
Mandibular plane to Frankfort plane	Downs	0°	7-23°		40 adults
	Mayne	0°	2-30°	$\pm .91^{\circ}$	30 adults
Angle of lower incisor to go-ga plane	Speidel	92.41	78-100°	$\pm 6.0^{\circ}$	
	Maryroba	90°			
	Downs	5°	8-27°	$\pm 5^{\circ}$	40 mixed
	Toothaker	64.04°	2-100°		30 adults
Union with upper first molar angle	Brodie	67.14°		$\pm .86$	
	M. yao	65.85°	50-75°	$\pm .50$	30 adults, children
	Baldridge	67.45° (Class I)		$\pm .87^{\circ}$	
		68.40° (Class II)		$\pm 3.5^{\circ}$	
		67.80 (Class II, Dev.)			
Union with go-ga plane angle	Mayne	67.05°	50.2-7	$\pm .85^{\circ}$	30 adults, children
	Baldridge	68.14° (Class I)		$\pm 3.65^{\circ}$	
		70.80° (Class II)		$\pm .82^{\circ}$	
		68.30° (Class II, Dev.)			
Union with go-ga plane angle	Mayne	79.00°	2-87°	$\pm 3.28^{\circ}$	30 adults
Union with go-ga plane angle	Mayne	51°	2-110°	$\pm 3.34^{\circ}$	30 adults
Facial angle	Downs	87.7°	82-95°		40 mixed
	Mayne	87.87°	78-94	$\pm 3.50^{\circ}$	30 adults
Angle of convexity	Downs	$\pm 0^{\circ}$	-8 to +6°		30 adults

of normals. Figure 5 shows the planes and landmarks used. Table II the selected normals for these criteria.

1 *Face height (Nasion-gonion)* The works of Brodie, Brash, Herzberg and Holic, Thompson and Mayne have established a constant ratio of about 43 per cent for nasal height or upper face height and 57 per cent for lower face height. This ratio seems constant from infancy and appears to be unaffected by most environmental influences. In this study face height was further broken down into the com-

ponents of the lower face—of prime concern because the insult has occurred in this area. Mayne found that maxillary height in 30 adults with normal dentitions averaged 41.66 per cent.

2 *Intermaxillary clearance or freeway space* This is the amount of space between the upper and lower teeth with the mandible in physiological rest position—a remarkably constant relationship established by facial masticatory and skeletal musculature when the mandible is not in active function. Thompson has found

this to average 2 to 3 millimeters in the anterior region in normal occlusion. Presence or absence of teeth does not affect this position.

3 *Frankfort mandibular plane angle* The angle formed by a line tangent to the lower border of the mandible extended posteriorly till it crosses the Frankfort horizontal plane (porion-orbitale) has been considered of significance in evaluating mandibular development especially ramus height. In his study on normals Downs arrived at a mean value of 21.9 degrees. Mayne used a line adjoining the anthropometric landmarks gonion and gnathion instead of a tangent and established a mean angle of 22.61 degrees.

4 *Angulation of mandibular incisors* This angle has been studied by numerous investigators following the emphasis placed upon it by Tweed as a clinical criterion in orthodontic case analysis and prognosis (31). All men have found the angle to be approximately 90 degrees.

5 *Nasion sella turcica mesiobuccal cusp of upper first molar* A rather constant angle of about 67 degrees is found in studies on normals. Specifically, any greater value would establish the molar in a posterior position while closing of the angle means a forward positioning of the molar or maxilla itself. In normal jaws the upper first molar falls almost exactly on a line from the sella turcica to the anthropometric landmark, gnathion—or chin point—on the mandible.

6 *Facial angle* The lower internal angle formed by the juncture of the Frankfort horizontal plane with a line from nasion to pogonion (or gnathion) gives a mean value of 87.7 degrees. This measurement determines the relative position of the chin point and thus anteroposterior growth of the mandible when compared to a constant plane—Frankfort horizontal. The same information can be got from the angle sella turcica nasion-gnathion using the S-A plane as a base plane instead of the Frankfort horizontal. The angular values are different naturally but both are constant. The determined mean for the latter is about 80 degrees.

7 *Angle of convexity (nasion point A pogonion)* This is another means of evaluating the position of the maxilla with respect to the

Fig. 5 Cephalometric and anthropometric landmarks and planes used in this study.

rest of the face and cranium. The angle formed by the lines joining these three measurepoints shows the degree of concavity or convexity of the profile. Downs found the mean value was ± 0 degrees. A minus reading indicates either a deficient maxillary contribution anteroposteriorly or an excessive mandibular accretion. It would then be necessary to examine other angular measurements of both maxilla and mandible to arrive at a differential diagnosis. A minus reading indicates a concave profile and a plus reading indicates a convex profile.

Each of the above criteria was carried through for all cases and the mean range standard deviation and standard error determined. These records are on file in the Orthodontic Department of Northwestern University. For this report, a master chart has been compiled giving the mean and range for each criterion as it compares to values arrived at in normals (Table III).

Face height was considered in order to see if there was any noticeable difference between cleft palate and normal cases. There is a broad range in upper face height with an excessive percentage contribution of upper face height. This does not necessarily mean that nasal height is greater but rather a lesser contribution of a component of the lower face. This seems to be the case as maxillary height is graphically deficient. All measurements here as well as in other criteria have been taken with the dental arches in occlusion with one exception. That exception is the amount of intermaxillary clearance at physiologic rest. All normal studies have been made with teeth in occlusion only. However a separate series of percentages and angular values have been determined in the cleft palate group with the

TABLE II—NORMAL CRITERIA FOR DETERMINING CRANIOFACIAL DEVELOPMENT

Criteria	Investigator	Mean	Range	S D	Material
Nasal height	Brash	41.5 ^{mm} (infants)			Skulls
		85 ^{mm} (adults)			
	Brodie	"			Normal children

mandible at physiologic rest but must await future similar studies on normals for a means of appraisal. It is of interest to note the similarity of physiological rest values in the cleft palate group to what might be considered a valid projection from normals with teeth in occlusion and allowing a normal intermaxillary clearance (Table IV).

The difference in the length of the line nasion gonathion in millimeters in physiolog-

ical rest and occlusion headplates determined the intermaxillary clearance. A very wide range can be noted and the mean of 7.3 millimeters is considerably more than the average values for normals. Apparently this substantiates the contention that the rest position is the result of muscular balance that it is extremely constant and subject to little change from birth to death. Maxillary or mandibular deficiency means a correspondingly greater in-

20 millimeters at 6, 7, and 8 years, respectively.

The value for the Frankfort mandibular plane angle is well within the central part of the range established for normals. However, there is some suggestion of a possible tendency toward a mandibular underdevelopment. As yet there is no apparent explanation why a maxillary insult should be reflected in lack of ramus height of the mandible.

The value of 79.6 degrees for the angle formed by the lower incisor to the mandibular plane is well below the means established by any investigator on normals. Some investigators would point to an abnormally short and tight upper lip reflected through decussating fibers of the lower lip in constant contact with the dental units as the logical reason (15, 25). The lingual tipping of the dental units helps to adjust the normally developed pattern of the mandible to the aberrant maxillary pattern thus reducing the apparent discrepancy.

The maxillary first molar shows a posterior positioning when compared to normal occlusions, with the angle nasion-sella-upper first molar becoming more obtuse. Further measurements involving the mandible (nasion-sella-gnathion, sella-nasion-gnathion, nasion-sella-gonion, and the facial angle) corroborate impressions gained from the Frankfort mandibular plane figures—namely that the mandible seems normal on the small side. The typically concave profile so often associated with cleft palate and cleft lip deformities is shown roentgenographically by a high negative angle of convexity of -8.2 degrees for the mean.

Table V is a comparison of the 8 cleft patients, not operated upon with the 14 complete cleft patients whose lips and palates have been surgically closed. The normal mean is included to facilitate evaluation. The mean values for maxillary height (item 2) and anteroposterior development (item 11) show an

even greater deviation from the normal in the patients operated upon than did the average of 45 cases of all types (Table III). The same measurements in the group not operated upon approach the normal means and fall well within the normal ranges. While the intermaxillary clearance (item 3) seems to be slightly excessive in the group not operated upon—4 millimeters—this is just about half the average of 8.1 millimeters in the surgically closed complete cleft group. Lower incisor and upper first molar readings also show less deviation from the normal means in the series not operated upon as opposed to the group operated upon. Judging from measurements designed

to be applied to the mandible there still seems to be a tendency toward a slight underdevelopment in this bony unit regardless of therapy or lack of therapy (items 4, 7, 8, 9, 10). Figure 9 shows for comparison the maxillary cast of a complete bilateral cleft lip and palate which had received no surgical treatment and the cast of the same type of cleft from a 13 year old boy who has had 15 surgical operations to provide a rock hard functionless flat fibrous diaphragm that successfully separates the nasal and oral cavities. Figure 10 compares the cast of the latter with that of a 5 year old girl who also has had no surgical correction of the palatal cleft. Figure 11 is an

*Mean values taken from cephalometric roentgenographic studies on normal groups by various investigators

anterior view of the same casts. Figures 12 and 13 show articulated maxillary and mandibular models and emphasize the anteroposterior malrelation of the patient operated upon when compared to the one not operated upon. Figures 14 and 15 are tracings of the patient operated upon taken at physiologic rest and occlusion again emphasizing the vertical and anteroposterior maxillary deficiency. *The evidence afforded by these comparisons would seem convincing proof of the damaging effect which can follow operations in early life if tissues which should be free to expand and develop are confined and restricted in a vise of heavy unyielding suture material and subsequent scar tissue formation.*

Nine of the present group had some degree of orthodontic therapy subsequent to surgical correction. Figures 16 and 17 show the cephalometric tracings in a patient with a result that would be considered a success clinically if casts were the only diagnostic aid. The upper and lower incisors are in normal mesiodistal relationship but there is a significantly high labial axial inclination of the maxillary incisors to bring them into normal interdigitation. This is combined with a large angle of profile concavity. Some observers would question the stability of this type of result where

lack of basal bone support reception of masticatory stress in an abnormal manner and constant pressure of a hypertonic upper lip make any hope of environmental balance a dubious one. It is quite likely in many cases that the tooth to basal bone relationship is more favorable before orthodontic treatment is undertaken and that instead of correcting malposed bony segments by moving bone itself (which can be done orthodontically) or ordinary orthodontic procedures move teeth through bones to a better occlusal relationship but a more unfavorable tooth to basal bone relationship.

SUMMARY

Certain salient impressions may be gained from this initial report.

1 The maxilla in cleft palate and cleft lip patients is deficient not only in its anteroposterior and lateral growth but also in its vertical growth. There is an abnormally large contribution of upper face height to total face height when the teeth are in occlusion due to the vertical maxillary deficiency. The high negative angle of convexity demonstrates specific lack of anteroposterior development.

2 There is a larger intermaxillary clearance or freeway space in cleft palate individuals. The variance from the normal becomes marked in complete cleft cases that have been corrected surgically. This would suggest that while there is a bony insufficiency, the general musculature, with the exception of those involved in surgical operations, attempts to maintain a normal developmental pattern and relation of parts.

3 Mandibular growth on the whole appears normal. Some lack of development is noted, but in any series of 45 individuals, a certain percentage will be found with similar problems. Mandibular underdevelopment is actually advantageous in some cases, reducing the disharmony resulting from a maxillary growth insult and thus improving facial balance. Mandibular overclosure, allowed by an excessive intermaxillary clearance is a consequence of the maxillary deficiency.

4 There is an excessive lingual axial inclination of the lower incisors to the mandibular plane. It need not be called teleological reasoning to look on a hypertonic orbicularis oris

muscle complex as a possible explanation. Any tightness of the upper lip is reflected through decussating fibers to the lower lip in constant contact with the dental units. The lingual positioning of the mandibular incisors reduces the underjet or the extent the maxillary incisors are abnormally posterior to the lower anterior segment, and hence should not be used as a criterion of maxillary development.

5 The maxillary first molar tends toward a posterior position with reference to cranio-metric measurepoints outside the maxilla.

6 We have seriously considered the propriety of early closure of cleft palates. It is becoming apparent that surgical correction will in some instances limit the growth potential of the maxillary denture (4/6ths of which are accomplished laterally by the end of the 4th year). In general the greater the number of operations the more marked the deviation from the normal. The apparently normal lateral and vertical growth in patients not operated upon where no limiting band of scar tissue is present would seem to substantiate this deduction.

7 The clinical results of orthodontic treatment while improving the tooth relationship in many cases do not necessarily stimulate basal bone development. Therapeutic results that are unstable have to be maintained in definitely

THE STABILITY OF AC GLOBULIN AND OF PROTHROMBIN IN CITRATED HUMAN PLASMA

JOHN L. FAHEY ARNOLD G WARE, Ph.D. and WALTER H. SEEGERS Ph.D.,
Detroit, Michigan

WITH the widespread use of stored blood a knowledge of the stability of the various plasma components concerned in the clotting mechanism has assumed increased value. Numerous investigators have reported studies on the change in plasma prothrombin during storage, but have arrived at somewhat contradictory conclusions (1 2 3 7 8 9 12 18). No reports have appeared on the stability of Ac-globulin a plasma globulin which accelerates the change of prothrombin to thrombin. The concentration of this substance in plasma like prothrombin is less than 0.5 per cent of the total plasma proteins (15). Ac-globulin is probably the same substance as factor V described by Owen (6) which was found to be absent from the blood of a certain patient with a bleeding diathesis which was not hemophilia (4 5). The absence of this factor from highly purified prothrombin preparations accounts for the slow rate at which these preparations are changed to thrombin even in the presence of optimum amounts of thromboplastin and calcium ions (16).

In a study of the exact role of Ac-globulin in blood clotting Ware Murphy and Seegers (14) came to the following conclusions: (a) Ac-globulin is inactive in circulating plasma under normal conditions. (b) At the inception of clotting Ac-globulin is first partially activated by extremely small amounts of thrombin formed from the interaction of prothrombin thromboplastin, and calcium. (c) The presence of small amounts of active Ac-globulin then catalyzes the interaction of prothrombin thromboplastin, and calcium. (d) The increased thrombin concentration further catalyzes the activation of Ac-globulin and the process proceeds co-autocatalytically to com-

plete the prothrombin activation process. The inactive form of Ac-globulin, present in the circulating plasma, is called "plasma Ac-globulin" by these investigators and the active form is called serum Ac-globulin. In order to include Ac-globulin the generally accepted theory of blood clotting has been modified to the following form:

Because Ac-globulin is fundamentally concerned with the activation of prothrombin it is important to learn how the concentrations of both of these substances are changed during storage.

PROCEDURE

Blood was obtained by venipuncture from normal adult human subjects. The first few cubic centimeters were discarded in order to reduce the possibility of contamination by tissue fluids, and the experimental sample was collected in a second syringe from the same needle. Two parts of 3.2 per cent sodium citrate solution contained in the syringe was used as anticoagulant for 23 parts of whole blood giving a final citrate concentration of 0.0087 M. After centrifugation at 1,000 revolutions per minute for 15 minutes at room temperature, the plasma was placed in a stoppered test tube in a refrigerator at 3 to 5 degrees C., and analyzed at intervals as indicated in Figures 1 and 2.

The prothrombin concentration was determined by the two stage method of analysis (11 17) and by a modification of this method

From the Department of Physiology Wayne University College of Medicine, and aided by grant from the United States Public Health Service, National Institute of Health.

Fig. 1. Change with storage time in the prothrombin concentration of citrated human plasma as measured by the stage method of analysis and by a modification of method.

Fig. 2. Change with storage in the mean Ac-globulin concentration of 5 samples of stored citrated human plasma.

(10) in which an optimum amount of accelerator factor is especially provided in the first stage of the determination. This special maneuver of supplying Ac-globulin becomes important in the two stage analysis when prothrombin is not already associated with an abundant supply of accelerator (6, 13, 14). In the original two stage method prothrombin is activated by the action of excess thromboplastin calcium and any Ac-globulin which happens to be present in the analytical sample. In the modified two stage method the supply of Ac-globulin is not left to chance. It is supplied in the form of bovine serum diluted 1:600. This amount assures a quantitative change of prothrombin to thrombin (10).

The method used for the determination of Ac-globulin employs the same reagents used for prothrombin analysis. In the actual determination a standardized solution of purified prothrombin is needed. Since it does not become activated by the two stage prothrombin reagents but does if Ac-globulin is added the rate of thrombin formation is a quantitative measure of Ac-globulin activity. Details of the test are described by Ware and Seegers (15, 16).

RESULTS

In 6 different experiments the prothrombin level of plasma as determined by the unmodified method of analysis remained constant for a period of about 7 days then decreased progressively to about 50 per cent of the original level at 21 days. A representative experiment

is presented in Figure 1. The prothrombin level determined by the modified method remained constant for the entire period of 21 days. In 5 different experiments mean values of which are shown on Figure 2 the plasma Ac-globulin remained constant for 7 days and then decreased to about a third of the original level after 21 days.

In several other experiments the prothrombin level was found by the modified method to remain unchanged for a period of 56 days.

In order to obtain information on whole blood a study was made of the stability of prothrombin and Ac-globulin by the same methods as previously described except that the blood was placed immediately in the refrigerator after mixing with the sodium citrate and without centrifugation. Plasma samples were removed for analysis from the supernatant plasma after the cellular elements had settled. Results similar to those obtained with citrated plasma were found for a period of 2 weeks for the stability of prothrombin in citrated whole blood. Ac-globulin was found to be somewhat less stable than in the centrifuged plasma. The decrease in activity began in less than a week. Studies with whole blood were not made beyond 2 weeks.

DISCUSSION

The apparent decrease in prothrombin level obtained with the original two stage method approximates the decrease in plasma Ac-globulin activity and appears to be attributable

to the interference of an γ -globulin lack in the quantitative prothrombin determination. This deficiency is corrected in the modified two stage analysis for prothrombin.

Since the 2 factors, prothrombin and γ -globulin were measured by methods which are considered specific and quantitative it follows that this study does not give information as to whether other clotting factors are altered. Reports in the literature (3, 7, 8, 9) show greater changes in stored plasmas. If those changes were due to prothrombin or γ -globulin there must have been a significant difference in the conditions of storage or the changes which those reports detected were concerned with fibrinogen or unrecognized clotting factors or both.

Stored blood as customarily used in hospitals, can then be considered as having full prothrombin content. A moderate diminution of γ -globulin activity occurs on storage of blood. The nature of this decrease is such that it need not be a matter of concern in the ordinary use of the blood bank.

SUMMARY

The prothrombin content of plasma obtained from blood which contains 0.0087 M sodium citrate as anticoagulant remains constant for at least 21 days when stored at 5 degrees C. The level of γ -globulin under the same conditions, remains constant for a week, decreases to about 55 per cent of the initial level in 2 weeks and to about 30 per cent in

3 weeks. The presence of formed elements has no effect on the stability of prothrombin. γ -globulin appears to be somewhat less stable in whole blood than in centrifuged plasma.

For reliable estimation of prothrombin by the two stage method it is necessary to supply γ -globulin if a sufficient quantity is not already associated with the prothrombin sample.

PULMONARY EMBOLISM

Its Incidence, Significance, and Relation to Antecedent Vein Disease

LEO M. ZIMMERMAN, M.D., F.A.C.S., DANIEL MILLER, M.D., Chicago, Illinois and
ALFRED N. MARSHALL, M.D., Portland, Oregon

DESPITE the recent welter of literature on the subjects of thrombosis and embolism, many aspects of the problem are still clouded by confusion and doubt. Numerous prophylactic and therapeutic measures have been promulgated the respective values of and indications for which are by no means agreed upon. Much of the data concerning this problem are based on clinical diagnoses which unfortunately, are subject to a wide margin of error. Any factual data which bear on this subject should be of value in dispelling the vagueness and confusion which still prevail.

In search for such information we have reviewed the pulmonary emboli observed in a large series of consecutive and unselected postmortem examinations performed over a 17 year period. Our study embraces the necropsy material of the departments of pathology of Michael Reese and Chicago Memorial Hospitals during the years 1930 to 1946 inclusive consisting of 538 consecutive examinations. These two hospitals which are served by a common department of pathology have a total capacity of 800 beds. All cases in which pulmonary emboli were found, irrespective of their size or significance were carefully studied from both the anatomical and clinical records. The information elicited throws light on the incidence and significance of pulmonary embolism and its relation to antecedent vein disease and supports the indications for various prophylactic and therapeutic measures.

During the years covered in this study there was a total of 9950 deaths in the 2 hospitals. Autopsy was done in 538 of these cases an over all incidence of 56 per cent postmortem examinations by permission. In view of the

relatively large series and the long period covered it was our opinion that statistics drawn from the 56 per cent of the fatalities which came to autopsy could be projected with a reasonably small margin of error to the remaining 44 per cent which did not. This projection would permit an estimate of the total number of emboli occurring in all the fatal cases. We recognize that there are two potential sources of error in such an estimate (1) It is possible that the families might be more reluctant to give permission for autopsy following sudden and unexpected deaths as from pulmonary embolism and that therefore the relative incidence of major embolism might be higher in the cases not having had autopsy. We know of no way of determining the validity of this criticism, but do not believe that it introduces a serious element of error. (2) More important is the fact that deaths resulting from trauma become coroner's cases and are not available for routine postmortem examination. This eliminates from our statistics those emboli which complicate fractures. This is a serious omission. However, despite these defects we believe our data to be more factual than are those based on clinical diagnosis alone.

In reviewing our data, it became immediately evident that it was necessary to divide the pulmonary emboli into several categories according to their significance. They fell rather readily into three fairly distinct classes. The largest group included those small emboli with or without pulmonary infarction which were purely incidental findings and which played no part whatever in the causation of the death of the patient. These were for the most part minute emboli often derived from mural thrombi in the cardiac chambers in persons who died of heart disease, pneumonias, cancer or other general causes. From the analysis of both the anatomical and the

From the Departments of Surgery and Pathology, Michael Reese and Chicago Memorial Hospitals, Chicago, Illinois.
Read before the Chicago Surgical Society, April 2, 1948.

bland thromboses and thrombophlebitis is somewhat tenuous. Most vein inflammations are accompanied by regional thrombosis and even the blandest thrombi provoke some degree of reactive inflammation of the adjacent vein wall. Nevertheless vein diseases fall quite generally into the three fairly definite types.

The most severe form of vein disease is the suppurative type of thrombophlebitis. These arise within or contiguous to areas of suppuration and the clinical picture is dominated by the manifestations of sepsis rather than by evidences of venous obstruction. Typical examples of suppurative thrombophlebitis are seen in lateral sinus thrombosis, secondary to mastoid suppuration in pyelophlebitis from purulent appendicitis and in the involvement of the perimetrial venous plexus in septic abortions or deliveries. Suppurative thrombi are not associated with major embolism but showers of small emboli from the liquefaction of the thrombus may give rise to multiple small mycotic infarcts and consequent pyemic abscesses.

The intermediate form of vein disease is the nonsuppurative thrombophlebitis. This condition is best typified by the familiar puerperal "milk leg." It is usually characterized by an abrupt onset often with chill and a rapid rise in temperature. There is very severe pain in the lower extremity and a rapidly developing generalized edema producing the picture of the tense white swollen shin leg. With this prototype in mind it is not difficult to differentiate the thrombophlebitic from the bland or phlebothrombotic type of venous occlusion. This last named disease has long been considered to be silent and asymptomatic. So emphatically have the younger physicians been impressed with the absence of clinical manifestations of thrombosis that when they do encounter the disease and find manifest evidence thereof they are inclined to question the diagnosis and suspect the existence of a thrombophlebitis.

It has long been recognized that these two vein diseases differ greatly in their tendency toward embolus formation. In thrombophlebitis the thrombus is fixed to the vein wall by an inflammatory reaction which is often of

such magnitude as to produce an extensive perivascular tumefaction. Not only is the clot adherent to the vein wall but the vein itself is baked to the surrounding tissues. Such thrombi have very little tendency to break loose and form emboli. However it must be remembered that appended to the inflamed thrombus there may be a propagating soft red thrombus which is not firmly attached to the vessel wall and which like any other bland thrombus may be the source of a major pulmonary embolus. In contrast to the inflamed thrombus described, the bland thrombus lies loosely within the vein lumen and often incompletely occludes it. Such thrombi are easily dislodged and readily form the source of emboli to the pulmonary vessels.

RESULTS

As has been stated a total of 5,588 autopsies were done in 9,980 deaths giving an over all postmortem percentage of 56 per cent. Pulmonary emboli of some degree were found in 345 of the 5,588 autopsies, an incidence of 6.1 per cent. It must be mentioned that ours is a general hospital population which includes a pediatric division. Approximately 40 per cent of the autopsies in our series were in children under the age of 15 in whom the incidence of pulmonary embolism is very low. This would tend to make our percentage of total pulmonary emboli lower than it would be if only adult autopsies were included. This does not however affect the actual number of emboli encountered which is of course the important consideration.

A breakdown of these emboli according to their significance and the type of vein disease from which they arose follows. Of the total of 345 cases of pulmonary embolism 166 were classed as purely incidental findings. These consisted as has been stated of very small emboli with or without infarction which played no part whatever in the cause of death of the patient. Of this group 154 emboli originated in bland thrombi and only 12 from infective phlebitides. Eleven of the latter number were of the suppurative type and constituted numerous minute infected emboli which were part of a general pyemic picture. Only one embolus in this incidental group

clinical findings, it was concluded that their role was purely incidental so far as the death of the patient was concerned, and they were included in the category designated as "incidental emboli."

A second group intermediate in size, comprised the emboli of a larger grade with perhaps larger infarctions, in which there was adequate explanation for the patient's death aside from the pulmonary embolism but in which it was conceivable that the embolus might have been a factor in weighing the balance against the possibilities of survival from a failing heart, an extensive pneumonia, a general infection or some debilitating disease. The designation contributory emboli has been applied to this group.

The third category were the fatal emboli in which it was believed that the death was due directly to the embolus.

It must be obvious that in an arbitrary classification such as this, there are certain borderline cases in which there may be question as to whether a small embolus might be entirely incidental and may not have contributed in some measure to the lethal outcome. At the other end of the scale also there may be an occasional case in which it might be difficult to state that the embolus was merely a contributory and not the chief factor in the death of the patient. Nevertheless in the overwhelming majority of cases reviewed the differentiation into the three categories afforded no difficulty whatsoever.

The criticism will probably be raised that the exact role of the embolus in the cause of death cannot be measured with any degree of accuracy and that, therefore this classification of emboli is not justified. We recognize of course, that size alone is not the only significant characteristic of the pulmonary embolus that relatively small emboli may produce severe circulatory disturbances, and even death by evoking spasm of the remainder of the pulmonary vessels, and possibly by reflex vagal disturbances as described by De Takats and his associates. Also in persons with failing circulation it is impossible to state just how much additional embarrassment from a pulmonary embolism or infarct would be required to weigh the balance against re-

covery. However it must be emphasized that we have studied the clinical as well as the autopsy records, and have considered the general condition of the patient, the nature and severity of the underlying disease, and the mode of death in arriving at our classification. Some element of personal equation in evaluating the data cannot be eliminated. Nevertheless we are convinced that gross error and misleading conclusions are inevitable if all emboli are lumped together without regard to their size and to the total clinical and pathological picture and that a division such as we have made, arbitrary though it may be, is essential if pulmonary embolism is to be placed in its proper perspective and if prophylactic and therapeutic measures are to be logically evaluated.

From a practical point of view the cases in the first two categories are those in which because of the gravity of the underlying disease, prophylactic ligations could not or would not have been done. In estimating the lives which might have been salvaged had this or the other measure been instituted, these could not be included. A somewhat similar division was made by Crutcher and Daniel in the material from Vanderbilt University Hospital with results comparable to ours. In this series of 2580 autopsies, 55 massive pulmonary emboli were found. Of these, 21 could not have recovered from their disease even though the embolism had not occurred.

In addition to the incidence and significance of the emboli we were greatly concerned with determining the relationship of the embolus to the antecedent vascular disease which gave rise to the embolus. It has long been recognized that vein inflammations and thromboses also fall into three fairly distinct categories, each of which carries a different degree of hazard of pulmonary embolism. In an earlier publication (6) we characterized these diseases as bland thromboses, nonsuppurative thrombophlebitides, and suppurative inflammations of the veins. Ochsner has subsequently given the name phlebothrombosis to the group of so called bland thromboses, and this designation has been generally accepted in the more recent literature. It must be recognized that the differentiation between

bland thromboses and thrombophlebitis is somewhat tenuous. Most vein inflammations are accompanied by regional thrombosis, and even the blandest thrombi provoke some degree of reactive inflammation of the adjacent vein wall. Nevertheless, vein diseases fall quite generally into the three fairly definite types.

The most severe form of vein disease is the suppurative type of thrombophlebitis. These arise within or contiguous to areas of suppuration and the clinical picture is dominated by the manifestations of sepsis rather than by evidences of venous obstruction. Typical examples of suppurative thrombophlebitis are seen in lateral sinus thrombosis, secondary to mastoid suppuration, in phlebitis from purulent appendicitis and in the involvement of the perimetrial venous plexus in septic abortions or deliveries. Suppurative thrombi are not associated with major embolism but showers of small emboli from the liquefaction of the thrombus may give rise to multiple small mycotic infarcts and consequent pyemic abscesses.

The intermediate form of vein disease is the nonsuppurative thrombophlebitis. This condition is best typified by the familiar puerperal "milk leg." It is usually characterized by an abrupt onset often with chill and a rapid rise in temperature. There is very severe pain in the lower extremity and a rapidly developing generalized edema producing the picture of the tense, white, swollen, shiny leg. With this prototype in mind it is not difficult to differentiate the thrombophlebitis from the bland or phlebothrombotic type of venous occlusion. This last named disease has long been considered to be silent and asymptomatic. So emphatically have the younger physicians been impressed with the absence of clinical manifestations of thrombosis that when they do encounter the disease and find manifest evidence thereof they are inclined to question the diagnosis and suspect the existence of a thrombophlebitis.

It has long been recognized that these two vein diseases differ greatly in their tendency toward embolus formation. In thrombophlebitis the thrombus is fixed to the vein wall by an inflammatory reaction which is often of

such magnitude as to produce an extensive perivascular tumefaction. Not only is the clot adherent to the vein wall but the vein itself is baked to the surrounding tissues. Such thrombi have very little tendency to break loose and form emboli. However it must be remembered that appended to the inflamed thrombus there may be a propagating soft red thrombus which is not firmly attached to the vessel wall and which, like any other bland thrombus, may be the source of a major pulmonary embolus. In contrast to the inflamed thrombus described the bland thrombus lies loosely within the vein lumen and often incompletely occludes it. Such thrombi are easily dislodged and readily form the source of emboli to the pulmonary vessels.

RESULTS

As has been stated, a total of 5,588 autopsies were done in 9,980 deaths giving an over all postmortem percentage of 56 per cent. Pulmonary emboli of some degree were found in 345 of the 5,588 autopsies, an incidence of 6.1 per cent. It must be mentioned that ours is a general hospital population, which includes a pediatric division. Approximately 40 per cent of the autopsies in our series were in children under the age of 15 in whom the incidence of pulmonary embolism is very low. This would tend to make our percentage of total pulmonary emboli lower than it would be if only adult autopsies were included. This does not, however, affect the actual number of emboli encountered which is, of course, the important consideration.

A breakdown of these emboli according to their significance and the type of vein disease from which they arose follows. Of the total of 345 cases of pulmonary embolism 166 were classed as purely incidental findings. These consisted as has been stated of very small emboli with or without infarction, which played no part whatever in the cause of death of the patient. Of this group 154 emboli originated in bland thrombi and only 12 from infective phlebitides. Eleven of the latter number were of the suppurative type, and constituted numerous minute infected emboli which were part of a general pyemic picture. Only one embolus in this 'incidental' group

lar fibrillation or from the ventricular walls at the sites of myocardial infarction. The presence of such mural endocardial thrombi does not rule out of course, the possibility of coexistent but unobserved thrombi in the veins of the lower extremities from which these small emboli may have derived their source. The leg veins were recognized as the second most frequent site of origin of the emboli in this group.

In the group of contributory emboli while the heart was still the source of a relatively large number of emboli the most frequent site of origin was the veins of the lower extremities. In the group of fatal emboli, almost all of the emboli arose from the veins of the lower extremities. The increasing frequency with which thrombi in the veins of the lower extremities constitute the source of embolism in the successively more serious groups of cases, is an expression of the role of size in the significance of pulmonary embolism. Large emboli must necessarily come from large vessels, and their bulk requires either great length or thick caliber. These conditions prevail particularly in the deep veins of the lower extremities. Massive emboli from other regions are extremely uncommon.

The various groups of pulmonary emboli covered in this study are further broken down in Table II according to whether they occurred in medical or surgical conditions. It will be seen that the smallest and least important emboli occurred almost twice as frequently in patients suffering from medical conditions as compared with those with surgi-

was thought to have arisen from a nonsuppurative thrombophlebitis.

Contributory emboli that is, emboli of a somewhat larger size, with or without infarction which may have contributed to a degree in the death of the patient occurred in 123 cases. Of these, 108 arose from bland thrombi 5 from nonsuppurative thrombophlebitis and 10 from suppurative phlebitis. In the last mentioned group the pyemic abscesses in the lungs which were of embolic origin were considered to have contributed toward the septic death of the patient.

Massive primary or fatal emboli were found in 56 cases in this series, an incidence of 10 per cent of all the autopsies. Fifty-three of these fatal emboli resulted from bland thrombi while 3 occurred in patients with nonsuppurative thrombophlebitis and none in instances of suppurative vein disease.

The source of the emboli as nearly as could be determined at autopsy is tabulated in Table I. It will be seen that in the incidental group of those in which a source was mentioned the most frequent site of origin was from the cardiac chambers themselves. They were thought to have broken loose from small mural thrombi in the auricular appendages in patients with cardiac decompensation or auricu-

TABLE III.—INCIDENCE OF FATAL EMBOLI
AFTER OPERATION

Total number of deaths	9,980
Percentage of permission postmortem examinations	56
Total number of fatal emboli found	56
Estimated total number of fatal emboli in all cases	100
Percentage of fatal emboli found at autopsy	1.07
Number of major operations performed	152,371
Number of postoperative emboli found at autopsy	43
Estimated total number of postoperative fatal emboli	77
Incidence of fatal emboli following operation	0.0005 or 1 in 2,000

cal diseases. In the intermediate group medical conditions still exceeded surgical ones, but the disproportion was somewhat less marked. In the group of fatal emboli the relationships were reversed, and surgical conditions exceeded medical by a ratio of 3 to 1.

In order to assay the actual hazard of pulmonary embolism in patients undergoing major surgical operations the number of fatal emboli found at autopsy in patients who had undergone surgery was compared with the total number of operations done during the time covered by this investigation. The records show that a total of 152,371 major operations were performed during these years. In the same period 43 fatal emboli were found at autopsy in patients who had undergone major surgical operations. It will be remembered that autopsy was done in 56 per cent of all the fatalities from all causes. Computed on this basis, it may be estimated that massive embolism was the primary cause of death in 0.05 per cent of patients undergoing major surgery—an incidence of 1 in 2,000 surgical operations (Table III).

Whether the fundamental illness which necessitates hospitalization is medical or surgical, it is usually recognized that old age, debility, and cardiac impairment are significant contributory factors in the etiology of pulmonary embolism. The age incidence in all emboli in this series irrespective of size or significance is recorded in Table IV. The infrequency of embolic accident in the first decades of life and the increasing incidence with advancing age, is borne out in our series. It will be noted that of the 313 cases in which the age of the patient

TABLE IV.—AGE INCIDENCE OF ALL PULMONARY EMBOLI

Years	Cases	Years	Cases
0 to 10	4	50 to 60	83
10 to 20	7	60 to 70	89
20 to 30	12	70 to 80	40
30 to 40	34	80 to 90	7
40 to 50	36	90 to 100	2

is stated, 171 (55 per cent) occurred during the two decades between 50 and 70 years of age.

The role of heart disease as a predisposing factor is stressed in most reported series of pulmonary emboli. In our study, cardiac disease, as the primary underlying disease, was recorded as follows. In the group of incidental emboli heart disease was present in 78 of 166 cases (48 per cent) in the contributory group it was found in 45 of 123 cases (37 per cent) while in the fatal emboli it was noted in only 2 of the 56 deaths (3.5 per cent). Thus it would seem that cardiac disease is an important predisposing factor in the less severe forms of pulmonary embolism but is of relatively minor significance in the etiology of major or fatal embolisms. However, it must be mentioned that myocardial impairment was listed as an associated anatomical finding in an additional 14 of the fatal cases. A very much closer relationship was noted in our series between fatal pulmonary embolism and malignant neoplastic disease. Of the 56 patients who died of pulmonary embolism not less than 20 were suffering from some form of malignant tumor. This confirms the role of debility and impaired general health in the predisposition to pulmonary embolism.

Seasonal and climatic variations are often listed as important predisposing factors in the etiology of pulmonary embolism. We were unable to find convincing confirmation of this impression. A breakdown of all embolic cases according to the months of the year is seen in Table V. No consistent pattern is seen.

TABLE VI.—SUMMARY OF 56 CASES

Surgical Case No. & P. Mactron No.	Age Sex Date	Official diagnosis	Treatment	Preoperative symptoms	Pathology at autopsy
(1) 31 M A 7 p903	44 F March	Ovarian cyst	Oophorectomy	5th day after operation suddenly became unconscious and died hours later	Thrombosis of right common iliac vein. Pulmonary embolism. Fatty infiltration of myocardium. At autopsy swelling of right leg was noted
(2) 32 A 193 B 609-17	70 M Nov	Hypertrophied prostate	Prostatectomy	1st day after operation sudden onset of difficulty in breathing, precordial distress and anxiety and cyanosis. Pulse irregular and rapid and feeble—arrhythmia. Died 5 hours after onset	Thrombophlebitis of left common iliac vein. Emboli in intrapulmonary branches of pulmonary artery which partially obliterated artery Thrombosis in left cardiac appendage. Early bronchopneumonia. Early pulmonary infarct. Atherosclerosis
(3) 33 A 5 B 45-30	48 F Dec.	Uterine fibroids	Hysterectomy Bilateral oophorectomy and subperitoneal developed parametrial postoperatively	5th day after operation, sudden attack of acute collapse, cold perspiration and gasping for breath. Fatty color, cyanotic but improved later 10th day after operation developed another attack as above; however, this time she died	Thrombosis left internal podosomal vein. Multiple large emboli right cardiac. Older and recent ridging emboli of pulmonary artery Pulmonary infarction Acute myocarditis with fatty infiltration. Chronic passive hypertension. No priors to cardiac tibia or femoral veins
(4) 34 A 234 B 564-35	44 F Nov	Fibrosis of uterus	Hysterectomy	7th day after operation, uneventful convalescence and allowed to walk 8th day after operation, patient washed in bathroom then morning and while at stool suddenly collapsed. Became cyanotic, gasped for breath and died in 5 minutes	Thrombosis of left posterior tibial vein Massive ridging pulmonary emboli. Recent infarct, left lower lobe. Embolus in right cardiac Left leg is larger than right.
(5) 35 A B 900	40 M May	Stomach accident— bruises and stricture of left side	Red root	Pain right chest 3 days 6th hospital day sudden onset of dyspnea, cyanosis, lost pulse fall in blood pressure, struggled violently for breath, and died one hour later	Old laceration of left lower leg Thrombosis of left femoral vein. Riding embolus in right ventricle extending into pulmonary artery Multiple emboli in smaller branches of pulmonary artery Infarction of lung
(6) 36 A 99 B 612-7	40 M Mar.	Carcinoma of stomach	Gastrectomy	1st day after operation, pain on breathing left lower chest. 5th day after operation cyanosis, poor pulse. Sudden onset of restlessness, gasping for breath, clutching at throat, marked cyanosis, cold, clammy and patient died in 15 minutes.	Carcinoma of stomach with perforation. Thrombosis right femoral vein. Pulmonary embolism. Both legs edematous, especially the right
(7) 37 A 103 B 609-18	40 F Nov	Carcinoma of the ovary	Right salpingo-oophorectomy Good postoperative course	6th day after operation sat up in chair. Patient had sudden attack of air hunger, pulse became poor and feeble, cold sweat, sallow hue, cyanosis, coma. Died 45 minutes after onset of attack	Thrombosis of left femoral artery Riding embolus both branches of pulmonary artery Right pitting edema of legs
(8) 38 M A 13 p907	41 M	Hyperplastic right femoral hernia	Operated upon and reduced	6th day after operation complained of faintness and died in 7 minutes while on bed pan	Recent surgical incision. Varicosis of superficial veins of lower extremities. Thrombosis of left femoral vein. Pulmonary embolus—massive chronic passive hypertension of lungs Acute pyelitis Early hemorrhagic infarction of lungs Fatty myocardium
(9) 39 M A	40 F Jan	Marked obesity Ovarian cyst	Removal of ovarian cyst Good recovery	9th day after operation complained of severe pain over left lower leg, arm and marked tremor. Sudden severe blood sugar rise. 10th day after operation labored, painful breathing, face cyanotic. 6th day after operation sudden attack of cyanosis, air hunger, incoherent pulse, and died in 5 minutes.	Recent surgical incision. Bilateral pulmonary emboli. Multiple infarcts of left lower lung. Emphysema. Fatty infiltration of right ventricle. Passive congestion. No source of emboli could be found even though thorough search was carried out

TABLE VI.—SUMMARY OF 56 CASES—Continued

Surgical Hosp. No. & P. Mortem No.	Age Sex Date	Clinical diagnoses	Treatment	Premonitory symptoms	Pathology & autopsy
(1) 10 A 110 C 7064	33 F Dec.	Fibroids of uterus	Hysterectomy	Uneventful postoperative course until 10th day after operation sudden onset of patient becoming cold and clammy pulseless no blood pressure. Heart tones poor and irregular. Died 1 hour 8 minutes after onset.	Thrombosis of iliac vein Massive embolus of main pulmonary artery
() 36 A 163 C 7133	45 F May	Cholelithiasis	Cholecystectomy	7th day after operation out of bed, 8th day after operation out of bed, suddenly felt faint, pulseless, cyanotic, cold and clammy. Died 15 hours later.	Massive pulmonary emboli No edema of legs. Varicose veins and ulcers
() 37 A 64 C 9087	65 M Feb.	Mesenteric thrombosis	Bowel resection. 10th day after operation patient had secondary clonus. Also developed wound infection and pneumonia during postoperative course.	Left leg noted to be swollen on 10th day after operation. Also on 10th day after operation patient suddenly began to perspire, gasped for breath, and became cyanotic and died in 5 minutes.	Generalized arteriosclerosis. Thrombosis superior mesenteric artery. Thrombosis left femoral vein. Massive pulmonary embolus. Marked coronary atherosclerosis. Healed infarct. Recent and organizing bronchopneumonia.
() 37 A 86 C 85	30 M Mar.	Fracture left femur	Closed reduction and immobilization in cast	On 11th day after operation patient was found dead. Had been talking to other patients 15 minutes earlier.	Fracture left femur. Thrombosis femoral vein. Massive pulmonary embolus. N. edema of legs.
() 37 A 64	4 F Oct.	Acute cholecystitis	Cholecystectomy	10th day after operation while on bed pan expelling emesis, patient suddenly became dyspneic, broke out in cold sweat, became cyanotic and died.	Recent embolus, pulmonary artery with complete occlusion of right and left pulmonary arteries. Multiple small pulmonary emboli in left upper lobe. Recent infarct in base of lower lobe. Recent thrombosis left femoral vein and right internal iliac vein.
() 37 A 78 C 90764	75 M Mar.	Incarcerated direct left inguinal hernia	Herniorrhaphy	8th day after operation helped into wheel chair; complained of dizziness, pulse became weak and patient became cyanotic. Died 4 hours later.	Massive pulmonary embolus. N. edema of legs noted.
(16) 37 A 70 C 15738	63 F Oct.	Carcinoma of the ovary	Exploratory laparotomy	11th day after operation patient had sudden attack of dyspnea, became cold, pulseless and cyanotic, and died 5 minutes later.	Thrombosis of deep veins of left lower leg. Massive pulmonary embolus. Edema of both legs.
(17) 383 0 C 4960	35 F Oct.	Fibroids of uterus	Hysterectomy	10th day after operation while walking became weak and dizzy pulseless, dyspneic and died 14 hours after onset.	Thrombosis right femoral vein. Embolus in main branch of right pulmonary artery. Embolus in left pulmonary artery. Right thigh larger than left.
(8) 38 A 77 C 47160	51 M Sept.	Diabetic gangrene and cellulitis	Left thigh amputation	10th day after operation sudden onset of cyanosis and dyspnea while talking to wife and fell back dead.	Secondary suppurative of wound of left thigh. Thrombosis right posterior tibial vein. Massive pulmonary embolus. Generalized arteriosclerosis.
(9) 38 A 34 C 45904	6 F Sept.	Carcinoma of duodenum	Gastroenterostomy Diffuse peritonitis upper abdomen. Stomach postoperative course.	11th day after operation up in chair and returning to bed suddenly seized with severe pain, nausea and dyspnea. Died in 5 minutes.	Adenoma of duodenum. Peritonitis. Thrombosis left renal vein. Pulmonary embolus. Pulmonary infarct.
(10) 38 A 133 C 5	37 F Nov.	Pregnancy	Cesarean section. 8th day postoperative wound disrupted and was resutured.	11th day after operation patient apprehensive. 14th day after operation slight cyanosis, tachycardia, dyspnea. 15th day after operation while on bed pan, patient suddenly went into shock. Blood pressure dropped to 80/50. Pulse weak and irregular and while being prepared for embolotomy she died. Attack lasted 1 hour.	Recent well healed incision. Edema of right lower extremity. Pulmonary embolus—main branch of pulmonary artery. Splenic hyperplasia.
() 38 A 98 C 40120	60 M Apr.	Carcinoma of sigmoid with perforation	Cecostomy and drainage	8th day after operation pulse in left lower chest. 11th day after operation friction rub—infarct? Pulse suddenly became imperceptible and patient died.	Massive pulmonary embolus. Thrombosis deep veins right leg. Bronchopneumonia.

TABLE VI.—SUMMARY OF 56 CASES—Continued

Surgical Hosp. No. & P. Mortem No.	Age Sex Date	Clinical diagnosis	Treatment	Premonitory symptoms	Pathology at autopsy
(30) 40 A 44 C 73357	56 F Nov	Acute cholecystitis	Cholecystectomy and appendectomy	Patient ran atypical course with weak pulse, temperature of 101° to 102° and 0.8° Dyspnea, and no cyanosis. 8th day after operation patient was improved. 12th day after operation patient suddenly became cyanotic and dyspnoic, pulse became rapid and weak and patient died within a few minutes.	Localized peritonitis at hilus and organized peritonitis in fossa of gall bladder. Hemorrhage over anterior surface of liver over posterior and lateral surface of colon. Phlebotrombosis left posterior tib- ial vein. Large embolus left pulmonary ar- tery
(31) 40 A 15 C 66014	7 F Apr	Diabetes Cellulitis right leg	Symptomatic treatment	While in hospital had a "stitching" pain across the lower chest and could not breathe. 7 days later patient was discharged from the hospital, and while on the way home in the taxi, patient sud- denly became short of breath, cold, cyanotic and died in 40 minutes. At autopsy left calf found to be larger than right leg.	Phlebotrombosis of left posterior tibial veins. Multiple pulmonary emboli, old and recent. Pulmonary hemorrhage right lower lobe. Generalized arteriosclerosis. Minute foci of bronchopneumonia
(32) 41 A 14 C 69438	4 M. Mar	Hernia	Hernia repair	Patient had bilateral hernia repair. Developed sharp pains in chest, grade worse by coughing. Also had elevated pulse. During following weeks patient had episode of chest pain, fever, blood-tinged sputum, pleural friction rub, dyspnea and tachypnea. 10th day after operation swelling of entire left leg noted and saphenous vein was palpated and a red streak was present in left thigh. 60th day after operation patient sud- denly died with attack of dyspnea, tachypnea, cyanosis, shock and weak irregular pulse	Recent organizing and canalized thrombi in left common iliac, en- teral iliac (external) and saphenous veins and deep waste canals. Multiple bilateral recent and or canalized pulmonary emboli. Recent and organized pulmonary infarcts of lower lobes. Organizing pleuritis lower left lobe. Swelling of entire left leg
(33) 4 A 73 C 0 50	45 F Mar	Intestinal obstruction	Exploratory laparotomy and at surgery large ovarian cyst was found tied to the de- scending colon which could not be removed. Patient went into shock after surgery and devel- oped peritonitis. Be- came distended and a resection was done	5 days after resection suddenly be- came dyspnoic and cyanotic and died in a few minutes	Propagating embolus of main pul- monary artery Swelling of both legs. Veins of pelvis thrombosed Adenocarcinoma of descending colon with marked narrowing of lumen. Acute fibrinopurulent peritonitis. Pyelonephritic and arteriosclerotic scars of kidneys
(34) 41 A 9 C 69432	64 M. Feb.	Cataract of left eye	Surgery for cataract of left eye	Postoperative course uneventful until 4th day. Temperature went to 101°. 6th day after operation patient felt chilly and became cold, clammy, perspired profusely. Pulse became rapid, weak and blood pressure fell. 7th day after operation another at- tack occurred with slight cyanosis. 8th day after operation temperature rose, and from then on started down. 20th day after operation patient be- came cyanotic, cold, clammy, rapid pulse and weak and died shortly thereafter. Patient also coughed up blood-tinged mucus prior to death. At autopsy left leg found to be larger than right leg	Phlebotrombosis of left hypogas- tric vein. Multiple massive pulmonary emboli Pulmonary infarction right lower lobe. Acute fibrinous pleuritis. Atherosclerosis of left lower lobe. Arteriosclerosis
(35) 4 A 83 C 109	67 F Apr	Carcinoma at junction of descending and sigmoid colon	Transverse colectomy	4th day after operation sudden onset of tachycardia to 120, tachypnea to 35. Preceded pain, dyspnea, cyanosis, slight cough and apprehen- sion. 7 days later patient had sudden attack of dyspnea, shallow respira- tion, cold clammy skin and death in an hour	Phlebotrombosis of left popliteal vein Multiple pulmonary emboli Primary adenocarcinoma of trans- verse. Hemorrhages with early infarcts of both lower lobes of lungs. Focal fatty degeneration of myo- cardium and myocardial fibrosis

TABLE VI.—SUMMARY OF 56 CASES—Continued

Surgical Hosp. No. & P. Mortum No.	Age Sex Date	Clinical diagnoses	Treatment	Premonitory symptoms	Pathology at autopsy
(41) 45 A 43 D 59645	51 F Feb.	Carcinoma of caecum	Resection of carcinoma and primary anastomosis	Patient went into shock following surgery and day after operation sutures were removed and patient developed a coughing spell and wound disrupted and had to be closed. 6th day after operation patient suddenly became cold and clammy with rapid respirations and died shortly thereafter.	Paleothrombosis of right common iliac vein. Papilliferous adenocarcinoma of the caecum. Large pulmonary embolus lodged in trunk of pulmonary artery. Multiple small emboli of lungs. Marked passive hyperemia of abdominal viscera. Thrombosis of branch of portal vein. Multiple myofibromas of uterus. Metastatic nodules in the liver.
Medical Hosp. No. & P. Mortum No.	Age Sex Date	Clinical Diagnoses	Treatment	Premonitory Symptoms	Pathology at Autopsy
(42) 31 A 188	67 M Sept.	Prostatic hypertrophy	Medical	After admission, had what appeared to be a typical attack of coronary occlusion. 4th day after admission, sat on commode to pass urine, no success, and returned to bed, was sitting up, suddenly head fell forward, became weak, cold clammy sweat, pale and died.	Early organizing thrombus of right femoral and iliac veins. Massive filling embolus of both pulmonary arteries. Hypertrophy and dilation of heart. No external evidence of edema of legs seen.
(43) 3 A 16 B 86064	64 M June	Carcinoma of pancreas; diagnosed at exploration 4 months previous	Medical	60 days after admission, patient was found dead while sitting on toilet.	Thrombosis of common iliac veins. Massive pulmonary embolus. Edema of both lower legs.
(45) 35 A 8 B 86065	47 M Feb.	Partial bowel obstruction	Medical	Found on floor of bathroom by nurse, semiconscious, rapid shallow respiration, pallor, pulse of 70, no blood pressure, and died one hour later.	Lymphosarcoma of stomach. Thrombosis left femoral vein. Bilateral pulmonary embolus. The left thigh is slightly larger in circumference than the right.
(47) 48 A 35 C 50	77 F Feb.	Arteriosclerosis	Medical	6th day patient went to washroom and on returning complained of epigastric pain, developed tachycardia, became cyanotic and died in 40 minutes.	Thrombosis right posterior tibial vein. Thrombosis left femoral vein. Multiple pulmonary emboli. Right leg slightly larger than left.
(48) 38 A 31	38 M May	Tubes dorsalis arthropathy Cord bladder	Medical	While receiving enema became cyanotic, breathing labored, pulse imperceptible died in 1 hour.	Tubes dorsalis. Acute suppurative arthritis left knee. Thrombosis of veins of calf of left leg. Massive pulmonary embolus.
(49) 30 A 06 C 64797	63 F Sept.	Hypertension and precordial distress	Bed rest at home 3 weeks prior to entry into hosp.	Had pain in left leg. Also had vertigoes and surrounding redness of left leg and induration and heat.	Old and recent thrombosis of superficial veins of left lower leg. Massive pulmonary embolus (left and right subdivisions of the pulmonary artery) and multiple emboli to radicles of both divisions of pulmonary artery. Multiple pulmonary infarcts. Mural thrombus right ventricle. Myocardial fibrosis.
(50) 41 A 41 C 64910	6 F May	Carcinoma of uterus	In hospital for observation. Had 2-3 year history of vaginal bleeding. Dyspnea, orthopnea, cough, ankle edema, hemoptysis.	While tiptoeing portable tray of abdomen, patient screamed, gasped, and died suddenly.	Primary polymorphous sarcoma of uterus. Paleothrombosis of right tibial vein. Recent and old embolism to both pulmonary arteries. Hypertrophy and dilation of heart.
(51) 41 A 38 D 35	43 M Oct.	Carcinomatosis	Symptomatic	Pain right lateral thigh 3 week. Severe epigastric pain. Blood pressure fell. Pulse rate increased and patient became cyanotic, cold and died suddenly.	Paleothrombosis of popliteal and calf veins right leg. Massive pulmonary embolus. Lymphosarcoma involving retroperitoneal, mediastinal, peritoneal and intracavitary nodes with extension to pancreas, gastroduodenal tract, esophagus and pericostae.

We were greatly concerned with the source of the embolism the type of vein disease which produced the embolus and the clinical signs of danger from impending embolic accident. The source of the embolus was not found in 7 cases and there were 3 additional cases in which the source was not found, but the leg veins had not been examined. The deep veins of the lower extremities gave rise to the embolus in 43 of the remaining cases and the prostatic, pudendal, and left renal vein each contributed one fatal embolus. There were no fatal emboli from thrombi or phlebitides in the superficial veins of the lower extremities.

As already stated 53 of the 56 fatal emboli arose from bland thrombi and in only 3 cases in this series was the diagnosis of thrombophlebitis made. In these 3 cases there was sufficient clinical evidence to support a diagnosis of deep vein thrombophlebitis of the lower extremities. In all of these however, the embolus was apparently a portion of non infected clot. It is entirely probable that in all 3 of these instances, a bland thrombus developed as a 'tail-part' to a thrombophlebitic process, and that it was this noninflamed non adherent portion which broke loose to constitute the embolus. These 3 cases are abstracted below.

CASE 29 No. 39 A 258—C 66766 White male aged 69 years entered the hospital because of prostatic hypertrophy. A suprapubic cystotomy was done on October 9, 1939. On October 13 while sitting up in chair patient had severe abdominal and back pain. On October 19 he complained of severe left chest pain while lying in bed. Also he had a rapid pulse at the same time. No swelling of legs was noted at this time. On November 5, 1939, the left leg became warm painful and edematous the left thigh measured 3 centimeters greater in circumference than the right thigh. He was treated with rest elevation and heat. The electrocardiogram reading was compatible with that for pulmonary infarct. On November 10 he suddenly gasped for breath and died.

Pathological diagnosis thrombophlebitis of left femoral vein multiple large riding emboli of pulmonary arteries old thrombi in smaller pulmonary arteries myocardial fibrosis benign prostatic hypertrophy suprapubic cystotomy.

CASE 32 No. 41 M A 14—C 69428 White male, aged 41 years, entered the hospital for a bilateral hemorrhoidectomy. He developed a sore throat after operation. Twelve days postoperative the patient developed sharp pains first in the right chest and later in the left chest which were made worse by

deep breathing or coughing. During the following weeks he had episodes of chest pain fever blood tinged sputum pleural friction rub dyspnea tachypnea and cyanosis at times. On the 19th postoperative day swelling of the entire left leg was noted the saphenous vein was palpable and tender and a red streak was present in the left thigh. About the 60th postoperative day the patient suddenly died with an attack of dyspnea, tachypnea, cyanosis and shock.

Pathological diagnosis Healed surgical incisions (2) for bilateral inguinal hernia recent organizing and canalized thrombi in left common iliac, femoral saphenous veins and deep vena comites of left leg with phlebosclerosis multiple bilateral recent and organized pulmonary emboli recent and organized pulmonary infarcts of lower lobes organizing pleuritis left lower lobe dilatation right ventricle edema left lower leg.

CASE 38 No. 42 A 271—D 19413 White male aged 38 years entered the hospital for the surgical removal of a right adrenal cyst. Ten days after operation the patient developed pains in the right calf with an elevation of temperature. The right leg was found to be swollen and tender. Thrombophlebitis was diagnosed and x ray treatments and immobilization were prescribed. Fever and swelling of the leg persisted and at times patient had chills. On the 20th postoperative day the patient had sudden, severe dyspnea with immediate pallor. He was given intravenous papaverine atropine intracardiac adrenalin coramine oxygen and artificial respiration, but the patient stopped breathing in 5 minutes and the heart stopped beating several minutes later.

Pathological diagnosis absence of right suprarenal gland thrombosis of right iliac and femoral veins massive pulmonary embolus acute and chronic passive hyperemia of lungs myocardial fibrosis uterolithiasis, multiple polyps of the rectum.

In a comparable group of 458 patients undergoing the same types of operation, 55 cases of thromboembolic syndrome were noted, with 26 instances of fatal pulmonary embolism. There was one embolic death in the ligated series. Allen therefore estimates that 25 lives were saved by the ligations in this small series of patients. Admitting that Allen's series constitute a selected group of patients from the standpoint of age, it is nevertheless striking that in our surgical material 52,000 consecutive major operations would be required to furnish the number of embolic deaths which he encountered in 458 cases! Similarly, Thebault and Ward recommend ligation of the inferior vena cava as the procedure of choice in thromboembolic disease. In their series of 36 cases there were 4 deaths and 2 additional deaths followed bilateral femoral vein ligations. The mortality and morbidity under this regimen should be weighed against the dangers of the disease without operation as revealed in our material.

The embolic cases in our series have been broken down according to whether the underlying illness was medical or surgical. It was found that in the less significant types of embolism medical conditions outnumbered surgical almost two to one. In the fatal emboli however there were almost three times as many surgical cases as medical. It has been pointed out that the incidence of death from massive pulmonary embolism following operation is far lower than we have been led to believe. Of the 152,371 major surgical operations performed during the period of this study, there was an estimated total of 77 deaths from pulmonary embolism. This gives an incidence of 1 in 2,000 operations and serves to indicate the actual postoperative risk from this complication. Whatever prophylactic and therapeutic measures are contemplated should be weighed in terms of the actual hazard which prevails. The relation of fatal embolus to antecedent vein disease aids in establishing the indications for the various therapeutic measures which have been advocated in thromboembolic disease. Inasmuch as almost all of the fatal emboli arose from bland thromboses our data confirm the long held belief that thrombophlebitic vessels carry

very little hazard of pulmonary embolism. On the other hand, the noninflamed, relatively asymptomatic bland thrombi constitute the source of real danger of embolic death.

The therapeutic implications from these facts seem clear. Phlebothrombosis is recognized as a serious threat of death from pulmonary embolism. Once formed further propagation of the thrombus can be prevented by the use of anticoagulants. This does not however, reduce the danger of embolism from the thrombus which is already present. The only safeguard against embolic death which we can offer in the presence of phlebothrombosis is the interruption of the venous trunk above the site of thrombosis.

Thrombophlebitis on the other hand carries with it very little risk of massive embolism other than that inherent in the possible bland thrombus which may extend by propagation from the phlebitic vein segment. Ligation therefore would not seem to be indicated. However, the use of anticoagulants to prevent the formation of a bland thrombus should serve to eliminate what little hazard exists in this condition. In view of the usual sudden onset of thrombophlebitis, its presence is announced by pain, fever, swelling and tenderness in sufficient time to permit the administration of anticoagulants for the prevention of phlebothrombotic extension.

On the basis of these general rules we have adopted the following regimen in the management of these vein complications. If a diagnosis of phlebothrombosis is made on the presence of local findings in the lower extremities, namely pain and soreness in the leg or foot, tenderness to pressure in the calf, pain on dorsiflexion of the foot (Homans sign) or edema, ligation is done at the level of the superficial femoral vein on the side presenting the findings. If there are no evidences of phlebothrombosis on the opposite side only a unilateral ligation is done. If present on both sides bilateral ligation is obviously indicated. Should the indications for ligation be a premonitory pulmonary infarction and should there be no local signs to indicate from which leg the embolus originated, one is compelled to do a bilateral ligation. As to the site for ligation as stated we consider the superficial

HEMOLYSIS DURING TRANSURETHRAL PROSTATIC RESECTION

CARL L. BIORN M.D., and LAURENCE F. GREENE, M.D., Rochester Minnesota

THE presence of excess amounts of free hemoglobin in the blood plasma of many patients immediately after transurethral prostatic resection has been recognized since Creevy and Webb reported its presence in a case in which oliguria and uremia developed after transurethral resection. They credited Emmett and McLaughlin with suggesting the possibility that sterile water used as an irrigating fluid during transurethral resection enters the circulation via prostatic veins and hemolyzes erythrocytes to an extent sufficient to damage the kidneys exactly as does a transfusion with incompatible blood. Subsequently McLaughlin and his co-workers reported 3 cases in which oliguria developed after transurethral resection. They found that the pathologic lesion in the kidneys in 1 of these cases was similar to the lesions observed in cases in which hemoglobinemia developed after transfusion with incompatible blood. Later Landsteiner and Finch reported significant post-operative hemolysis in 10 of 15 patients who underwent transurethral resection.

The purpose of this paper is threefold. First we intend to review the fundamental research and knowledge on which the present concept of hemoglobinemia and hemoglobinuria is based. Second we wish to report the results obtained from our study of 100 patients on whom determinations of plasma hemoglobin were done immediately after transurethral resection. Last we will interpret the results of our study on the basis of concepts of hemoglobinemia previously reviewed.

PATHOLOGIC PHYSIOLOGY OF HEMOGLOBINEMIA AND HEMOGLOBINURIA

Normal disposition of hemoglobin. Normally in the adult human being approximately 19 per cent of the circulating erythrocytes are destroyed each 24 hours, this destruction re-

sults in the liberation of between 7 and 8 grams of hemoglobin each day. Destruction of these erythrocytes with release of hemoglobin takes place within the cells of the reticulo-endothelial system. From this released hemoglobin the reticulo-endothelial cells metabolize bilirubin which is subsequently excreted by the liver. Theoretically, this process is an intracellular one and the hemoglobin does not escape into the circulating blood plasma. Actually however, 100 cubic centimeters of normal human plasma contains 2 to 5 milligrams of free hemoglobin that is pigment derived perhaps from actual intravascular destruction of erythrocytes (44).

Disposition of free hemoglobin in the plasma. When an abnormal quantity of free hemoglobin is present in the plasma the reticulo-endothelial cells continue to convert this pigment to bilirubin (44). However, if the hemoglobin is liberated faster than its conversion to bilirubin then hemoglobinuria may occur. Similarly, if the amount of bile pigment formed is greater than can be excreted by the liver, retention of this product in the plasma results in hemolytic jaundice (5).

After intravenous injection of hemoglobin into dogs, Gilligan and associates found that less than 15 per cent of the total was excreted in the urine. Flink found when he injected larger quantities of hemoglobin intravenously that 25 to 40 per cent of the total hemoglobin in the plasma was so excreted. In one of their patients O'Shaughnessy and his associates reported that 20 per cent of the total amount of circulating hemoglobin in the plasma was excreted in the urine. Supposedly the remaining 60 to 85 per cent of hemoglobin in the circulating plasma is metabolized by the reticulo-endothelial cells into bilirubin excreted later by the liver or retained in the plasma.

Hemoglobin is removed from blood plasma fairly rapidly. Gilligan and his co-workers injected hemoglobin into human beings and determined the length of time required to clear

From the Section on Urology Mayo Foundation and Mayo Clinic.

the plasma of hemoglobin. They found that if the concentration of hemoglobin was 40 to 60 milligrams per 100 cubic centimeters of plasma, 5 hours were required for its value to return to normal when the concentration was 130 to 225 milligrams per 100 cubic centimeters, 8 hours, and when it was 280 to 380 milligrams, 12 hours. In other words, the higher the concentration of hemoglobin in the plasma the longer the clearance time.

When hemolysis is extensive the concentration of hemoglobin in the plasma rises until hemoglobin appears in the urine. A definite renal threshold for the excretion of hemoglobin has been determined for both man and dog. Monke and Yule could not detect any hemoglobin in the urine of dogs as long as the level of plasma hemoglobin remained less than 80 to 100 milligrams per 100 cubic centimeters when the concentration was higher however hemoglobin appeared in the urine. In man Ottenberg and Fox found the renal threshold for the excretion of hemoglobin to be variable. In some persons hemoglobinuria developed when the level of hemoglobin was 110 milligrams per 100 cubic centimeters of plasma in other persons even though the plasma hemoglobin attained levels of 200 to 288 milligrams per 100 cubic centimeters, no hemoglobin appeared in the urine. Similarly Gilligan and his associates observed hemoglobin in the urine of those human beings who had concentrations of plasma hemoglobin of more than 135 milligrams per 100 cubic centimeters.

PATHOLOGIC RESULTS OF HEMOGLOBINEMIA AND HEMOGLOBINURIA

Our main interest in hemoglobinemia and hemoglobinuria is to determine whether the presence of free hemoglobin in plasma is harmful to patients undergoing transurethral resection. Some evidence concerning such a possibility may be gathered by reviewing the experiences of others who have injected hemoglobin into animals and man.

Results from injection of hemoglobin in man. Ellards and Minot and Ottenberg and Fox injected hemoglobin intravenously into human beings and noted either a mild reaction characterized by a chill with subsequent hot and cold flushes or no reaction at all.

O'Shaughnessy and associates, Fairley and Gilligan and co-workers observed untoward reactions characterized by chills, fever, nausea, abdominal cramps, pain in the back and loins and sensations of constriction in the chest following the intravenous injection of a solution containing hemoglobin. These symptoms parallel those noted in clinical hemolytic syndromes. However no one has reported injecting sufficient hemoglobin into human beings to cause renal damage with oliguria similar to that in clinical hemolytic states. Amounts of hemoglobin sufficient to produce renal damage have been injected into animals.

Experimental production of renal damage by injection into animals of solutions containing hemoglobin. Ponfick produced hemoglobinuria by injecting heterologous blood into animals. He found pigmented casts deposited in the renal tubules of these animals.

Levy and Yorke and Nauss succeeded in reproducing renal damage similar to that observed in blackwater fever by injecting solutions of pure hemoglobin and homologous and heterologous laked blood into rabbits.

Baker and Dodds produced a marked rise in the values for nonprotein nitrogen in the blood of rabbits with acid urine by the intravenous injection of hemoglobin but noted no such phenomenon when the urine was alkaline. They concluded that precipitation of hemoglobin pigment in acid urine caused mechanical obstruction of renal tubules and resulted in suppression of urinary excretion.

DeGowin and co-workers (14, 15) showed that a high percentage of dogs with strongly acid urine succumbed to transfusions of large amounts of laked red blood cells while death did not follow similar injections if the urine of the animal was alkaline. The cause of death was uremia and pathologic examination of the kidneys disclosed changes similar to those found in other types of oliguria.

Most recently Flink injected high dosages of hemoglobin intravenously into dogs that had either acid or alkaline urine and produced renal insufficiency in both. He found that the development of renal insufficiency in these dogs depended on the concentration of hemoglobin in the plasma immediately after the injection of the hemoglobin. An initial con-

centration of 3,700 milligrams of hemoglobin per 100 cubic centimeters of plasma or more was noted in all of the dogs in which renal insufficiency developed

THE OLIGURIA SYNDROME

We will consider the oliguria syndrome, that is, primary oliguria and its associated symptoms in some detail because the coincidental occurrence of hemoglobinemia and oliguria in patients who have undergone transurethral resection has stimulated the belief that hemoglobinemia may be an important factor in causing the oliguria.

Oliguria following transurethral resection usually develops in cases in which the surgeon has encountered some difficulty such as rupture of the prostatic capsule excessive hemorrhage or opening of periprostatic venous sinuses. In such cases, typical oliguria or anuria may develop. A progressive rise in the concentration of nitrogenous waste products in the blood occurs. Early the patient may suffer from anorexia, nausea and vomiting but as the syndrome progresses these symptoms usually disappear and the patient feels relatively well. Many of these patients die of renal insufficiency but some ultimately excrete urine and recover spontaneously.

The oliguria syndrome following transurethral resection is not different in any respect from the oliguria syndrome known to occur in a wide variety of acute illnesses. Oliguria is associated with pigment in the patients' blood and urine in blackwater fever (4, 24, 50), hemolytic transfusion reactions (2, 15, 16, 24), severe burns (46), obstetrical mishaps (39, 52), acute hemolytic anemia secondary to sulfonamide therapy (23) and the crush syndrome (8-10, 18). Macgregor, Havard and Parsons have examined the literature however and found that the syndrome develops in many conditions in which abnormal pigment may be absent from the urine. These may include the alkalosis of gastric tetany, septic abortion, cholera, yellow fever, diabetes, the hepatorenal syndrome, traumatic uremia, carbon monoxide poisoning, and pernicious anemia. Creevy also has pointed out that postoperative uremia may be due to acute pyelonephritis prolonged severe hypotension, caused by

hemorrhage, anesthesia or surgical shock, or to trauma to the ureteral orifices with resultant hydronephrosis.

Pathologic changes found in the kidney at necropsy in those cases in which patients died from this syndrome are strikingly similar no matter what the initial illness was (2, 7, 15, 26, 32). Characteristically, the glomeruli appear almost normal, some edema and cellular infiltration of the interstitial tissue may be present, but the outstanding changes are in the renal tubules. Degenerative changes occur especially in the loops of Henle and the distal convoluted tubules, and these may vary from mild vacuolization to necrosis and desquamation of cells. Granules of varying size may be noted in the epithelial cells of the convoluted tubules. Deposits of calcium in the degenerated tubules and signs of regeneration of epithelial cells have been found. At times a variable number of deeply pigmented casts appear in lumina of loops of Henle, distal convoluted tubules and the collecting tubules.

The mechanism of the development of this syndrome is not definitely known. The four main theories are (1) mechanical blockage of renal tubules, (2) a humoral nephrotoxic substance, (3) renal anoxia and (4) renal arteriovenous shunts.

The concept of mechanical blockage by precipitation of hemoglobin pigment in the renal tubules is based on experimental work on the development of renal insufficiency after the injection of hemoglobin in animals with acid urine (3, 4). Theoretically, hemoglobin is thrown out of solution when the intratubular fluid becomes sufficiently acid and when simultaneously through absorption of water the concentration of sodium chloride is increased to about 1 per cent. These requirements are met in the lower nephron (that is the distal loop of Henle and the distal convoluted tubules) and in the collecting tubules the sites where cast formation is usually found (32).

Many investigators agree with the theory of mechanical obstruction but some believe that cast formation is secondary to the tubular epithelial degeneration and is not the cause of renal insufficiency per se (2, 16, 26). Experimentally Yuile, Gold, and Hinds showed that hemic pigment is precipitated in tubules pre-

viously damaged by ischemia or by chemical poison. Their results indicate that precipitation of casts coincides with tubular damage. Bling has shown that renal insufficiency may develop without the precipitation of pigmented casts within the tubules. Flink produced renal insufficiency by injecting large doses of hemoglobin into dogs having either acid or alkaline urine. Clinically fatal anuria following hemolytic transfusion reaction has occurred in the human being despite alkalization of the urine and is no more common in blackwater fever in patients with acid than in those with alkaline urine (16 24 53).

The theory that some vasospastic or nephrotoxic substance released into the circulation induces renal damage and insufficiency is frequently mentioned but remains nebulous. DeGowin and co-workers (15) concluded that some factor other than tubular obstruction causes renal changes in this syndrome because in most of their 9 cases of 'transfusion kidney' not enough tubules were obstructed to produce any important diminution in renal function. They postulated that a substance toxic to kidneys may be liberated by intra-vascular hemolysis.

According to the renal anoxia theory renal damage is caused by diminished supply of oxygen to the kidneys resulting from disturbance of renal blood flow which follows peripheral circulatory failure. The blood flow in the kidney can vary independently of the general circulation so that while the total volume of circulating blood may decrease in shock to approximately half of the normal value, the flow of blood through the kidney may decrease to one-tenth one-twentieth, or even less of the normal flow (30 43 49). Various investigators including Phillips and associates and Corcoran and Page (11) have observed vasoconstriction of renal blood vessels during hemorrhagic shock to the point of almost complete absence of renal circulation. Such reduction of flow not only leads to diminished filtration force within the glomerular capillaries but also to diminished peritubular circulation and reduction in essential oxygen supply with consequent tubular damage. The presence of an excess amount of hemoglobin in blood plasma also may contribute to this renal

anoxia by producing vasoconstriction since a definite shrinkage of the kidney has been detected immediately after the intravenous injection of laked red blood cells in the dog by Levy and of hemoglobin solution in the dog and frog by Mason and Mann and in the dog by Hesse and Platov. Apparently the duration of ischemia is an important factor in determining the extent of renal injury. Van Slyke for example has shown that severe reduction of the renal blood flow during circulatory failure for a period of hours following hemorrhage is often followed by markedly impaired renal function and pathologic changes in the kidneys consisting chiefly of tubular necrosis and the presence of pigment casts in the tubules. These are changes not unlike those described in the oliguric syndrome of human beings. Supposedly oliguria develops when tubular cells are damaged to such an extent that reabsorption of glomerular filtrate becomes unselective (17 32 42). In other words, the permeability of the necrotic cells is altered so that the osmotic pressure of the blood in the peritubular capillaries is able to draw back all or practically all of the normal glomerular filtrate and a scanty volume of urine is passed.

More recently Trueta has demonstrated that in certain oliguric states the blood passes from artery to vein through arteriovenous shunts in the kidney in this manner the blood does not reach the renal cortex.

Thus, hemoglobinemia during transurethral resection may be one of several factors inducing oliguria following resection by tubular obstruction nephrotoxic effect or vasoconstriction.

HEMOLYSIS DURING TRANSURETHRAL PROSTATIC RESECTION IN 100 PATIENTS

Since hemoglobinemia in patients is known to follow transurethral resection we have been investigating the incidence of hemoglobinemia, the factors which may accompany or predispose to its development, and the possible postoperative ill effects in cases in which hemoglobinemia follows transurethral resection. This report is based on a study of 100 cases in which the concentration of plasma hemoglobin was determined after transurethral prostatic resection at the Mayo Clinic.

TABLE I — VALUES OF PLASMA HEMOGLOBIN IN 100 CASES AFTER TRANSURETHRAL PROSTATIC RESECTIONS

Plasma hemoglobin, mgm. per 100 c.	Type of estimation		Total cases
	Quantitative	Qualitative	
50 - 100	6		6
30 - 400*	6		6
10 - 300	3		4
— 200	3		4
10-100	8	8	16
0-15	20	35	55

*No values from 40 - 300 mgm. in our series.

TABLE II — POSTOPERATIVE VALUES OF PLASMA HEMOGLOBIN IN RELATION TO CONDITION FOR WHICH PROSTATIC RESECTION WAS PERFORMED

Condition	Plasma hemoglobin, mgm. per 100 c.c.	
	5 or less	More than 5
Benign prostatic hyperplasia	27	5
Carcinoma of prostate	5	4
Contracture of vesical neck		
Vesical neoplasm with extension to prostate		
Total cases	44	9

Method of study The method of study has been as follows. The concentration of hemoglobin in the plasma was determined in 100 cases taken at random from those in which transurethral resections were performed at the clinic during the months of April to July, 1947. The incidence of hemoglobinemia in this series was calculated and any factors which may possibly accompany or predispose to hemoglobinemia were studied. These factors included the weight and nature of the tissue resected, the loss of blood and the difficulty of resection reported by the surgeon. Finally the series was analyzed for such possible postoperative ill effects secondary to hemoglobinemia as fever, chill, gastrointestinal symptoms and oliguria after resection.

The technique for determining the quantity of free hemoglobin pigment in the plasma was adapted from that of Flink and Watson. This method depends on conversion of derivatives of hemoglobin pigment to pyridine ferrohemochromogen whose absorption is measured with a photoelectric colorimeter which has been calibrated previously with known quantities of hemoglobin. In order to avoid artificially induced hemolysis the blood must be collected carefully. We used a dry syringe with a close fitting 19 gauge needle and took precautions to draw the blood slowly and carefully. Collapse of the vein wall on the needle, circulation of air bubbles in the blood or too rapid withdrawal of the blood all induce artificial hemolysis. The blood was then gently emptied into a graduated centrifuge tube which contained either 0.5 cubic centimeter

of 3 per cent solution of sodium citrate or powdered heparin. The blood and anticoagulant were mixed by careful inversion and centrifuged. When heparin was used as an anticoagulant we obtained best results by dusting a small quantity on the portion of the syringe plunger which was in contact with the blood. We departed from Flink's technique in that we used a Kolmer colorimeter instead of an Evelyn and also used slightly different quantities of plasma and reagents. When larger amounts of plasma than 0.5 cubic centimeter were employed we encountered difficulty with turbidity. Consequently, 0.1 to 0.5 cubic centimeter of plasma was placed in a colorimeter tube. To this was added sufficient amount of 1 per cent solution of ammonium hydroxide to bring the volume to 4.5 cubic centimeters. The volume was then increased to 6.0 cubic centimeters by the addition of 0.5 cubic centimeter of pyridine and 1.0 cubic centimeter of a 2 per cent solution of sodium hyposulfite ($\text{Na}_2\text{S}_2\text{O}_4$) freshly prepared in 1 per cent solution of ammonium hydroxide. A duplicate tube was set up in a similar manner with 0.5 cubic centimeter less of ammonium hydroxide to allow for the addition of 0.5 cubic centimeter of hydrogen peroxide and 5 minutes were allowed for decolorization. Then, after the center setting of the colorimeter was determined by use of the duplicate tube, the galvanometer reading of the unknown solution was determined. By applying this to the calibration curve the hemoglobin content of the specimen was calculated.

Actually hemolysis of any significant amount can be estimated by gross examina-

TABLE III.—POSTOPERATIVE VALUES OF PLASMA HEMOGLOBIN IN RELATION TO SURGICAL FACTORS

Plasma hemoglobin, mgm per 100 c.	Cases	Average weight of tumor, gm	Average blood lost, cc	Operative difficulties, per cent
25-50	6	26	265	100
50-100	6	30	105	67
100-200			497	75
200-500	14	41	998	30
500-1000	10	5	242	20
Over 1000	44	20	22	80

tion of the patient's plasma after the blood has been centrifuged. The color of the plasma reflects the concentration of hemoglobin pigment. Thus, when expressed in approximate values, yellow plasma contains little or no hemoglobin, yellow with a slight pink tinge contains 25 to 30 milligrams, orange 30 to 65 milligrams, and pink 65 to 125 milligrams per 100 cubic centimeters. When more than 125 milligrams is present, the plasma is colored gradually deepening shades of red.

Results of investigation. Of the 100 patients in this series, 44 had 25 milligrams or less of hemoglobin per 100 cubic centimeters of plasma and 56 had levels above this figure (Table I). We used 25 milligrams per 100 cubic centimeters as a dividing point because gross hemolysis is first visible at this concentration and some of our determinations are based on gross observations only. (The actual upper limits of normal for plasma is 5 milligrams per 100 cubic centimeters.) The incidence of hemolysis in relation to the nature of the obstruction for which transurethral prostatic resection was performed is listed in Table II. The incidence of hemolysis was essentially the same for both benign and malignant lesions of the prostatic gland. Sterile water was used as the irrigating solution in all cases of this series. In a small group of patients not included in this study however both glycine and physiologic saline solution were used as irrigating solutions without appreciable postoperative hemolysis.

The operative factors which may accompany or predispose to hemoglobinemia are summarized in Table III. This table shows that the average weight of tissue removed in

cases in which the level of plasma hemoglobin after operation was more than 25 milligrams per 100 cubic centimeters was greater than in cases in which it was 25 milligrams or less. However the general rule that hemolysis occurs more commonly after removal of larger amounts of tissue is not invariable because in 2 cases of the series in which 9 and 7 grams of tissue were removed, the concentration of plasma hemoglobin after operation was 516 and 204 milligrams per 100 cubic centimeters respectively. On the other hand each of 4 patients in the group with little or no hemolysis had 50 grams or more of tissue removed.

In general the average volume of blood lost at operation has been found to be higher in those cases in which the level of plasma hemoglobin was more than 25 milligrams per 100 cubic centimeters than in other cases. There were exceptions to this general rule also. Three patients who lost 45, 40, and 30 cubic centimeters of blood at operation had postoperative concentrations of hemoglobin of 384, 335 and 372 milligrams per 100 cubic centimeters of plasma, respectively. Conversely 4 of those who did not have appreciable postoperative hemolysis lost more than 300 cubic centimeters of blood at operation.

The difficulty of resection and the level of postoperative hemoglobinemia appear to be definitely related. The surgeon encountered difficulty in 50 to 100 per cent of the cases in which the concentration of plasma hemoglobin after operation was more than 100 milligrams per 100 cubic centimeters. By contrast, the surgeon reported difficulty in only 20 per cent of all cases in which the postoperative level of plasma hemoglobin was less than 100 milligrams. The difficulties encountered by the surgeons in these cases are detailed in Table IV. This table shows that in all 6 cases in this series in which the postoperative concentration of plasma hemoglobin was more than 500 milligrams per 100 cubic centimeters the operations were performed with difficulty. In 4 of the 6 cases operative bleeding was controlled with difficulty in 1 case perforation of the urethra and in 1 opening of a definite venous sinus occurred. Similar difficulty was encountered during operation in 4 of the 6 cases in which the postoperative level

of plasma hemoglobin was between 300 and 400 milligrams in 3 of the 4 cases in which it was between 200 and 300 milligrams, and in 7 of the 14 in which it was between 100 and 200 milligrams. By contrast, the surgeon encountered difficulty during the operation in only 5 of the 26 cases in which the postoperative concentration of plasma hemoglobin was from 26 to 100 milligrams and in 8 of the 44 cases in which it was 25 milligrams or less. Excessive bleeding, opening of venous sinuses, and pocketing of the gland were the difficulties most frequently encountered.

Our investigation of possible postoperative reactions secondary to elevated concentrations of plasma hemoglobin in this series was confined to study of postoperative fever, chills, gastrointestinal complaints, and oliguria. A temperature of 101 degrees F was chosen arbitrarily to represent a fever and only the fever and chill occurring on the first postoperative day were considered in this study because the febrile reaction caused by the accumulation of hemoglobin in plasma is known to appear within a short time after the development of hemoglobinemia. We considered the gastrointestinal symptoms including anorexia, nausea, and vomiting which occurred within the first few postoperative days. Our estimation of oliguria was based on volume of urinary output during the first 4 days.

TABLE V — POSTOPERATIVE VALUES OF PLASMA HEMOGLOBIN IN RELATION TO POSTOPERATIVE COMPLICATIONS

Plasma hemoglobin, mgm. per 100 c.c.	Cases	Chill	Fever	Gastrointestinal symptoms	Oliguria

401-500	6			5	
501-600	44			6	1*

*Not true oliguria syndrome as described in text.

As shown in Table V postoperative chill did not develop in any of the 100 cases. Eleven of the 44 patients who had 25 milligrams of hemoglobin or less had fever while only 6 of the 56 patients who had hemoglobinemia above this level had such fever. This comparison appears to show that concentrations of plasma hemoglobin found in this series do not cause postoperative fever and chill. On the other hand the column of this table devoted to the incidence of gastrointestinal symptoms following transurethral resections shows that these symptoms occur more frequently in cases in which the postoperative level of plasma hemoglobin is high. For example in more than 80 per cent of those cases in which the concentration of plasma hemoglobin was between 200 and 1,000 milligrams per 100 cubic centimeters postoperative anorexia, nausea, and vomiting occurred as compared with 37 per cent of those cases in which the level of plasma hemoglobin was 25 milligrams or less.

None of the patients in this series developed the oliguria syndrome regardless of the postoperative level of plasma hemoglobin. There was 1 death in this series and although the urinary output was low in this case it obviously did not fall into the group of cases in which the oliguria syndrome as previously described occurred. This patient was a white man 77 years old who had arteriosclerotic heart disease, auricular fibrillation and rheumatoid polyarthritis, in addition to obstruction at the vesical neck. Risk of operation was considered great, but after 40 days of preparation, transurethral prostatic resection

TABLE VI.—URINARY OUTPUT OF 6 PATIENTS WHO HAD HIGH POSTOPERATIVE VALUES OF PLASMA HEMOGLOBIN

Patient	Plasma hemoglobin, mgm per 100	Daily urinary output on 5 postoperative days			
		1st	2nd	3d	Average
	783	1,300	2,415	2,460	2,058
	564	1,800	700	90	1,190
	1,030	800	1,900	2,400	1,713
	115	90	1,000	1,800	1,030
		1,800	2,100	1,500	1,800
6	523	1,125	1,000	1,800	1,312

was performed. A diagnosis of contracture of the vesical neck, multiple prostatic calculi and chronic prostatic abscess was made at that time. During resection an old prostatic abscess was unroofed and a total of 2 grams of tissue was removed. The postoperative value of plasma hemoglobin was less than 25 milligrams per 100 cubic centimeters. The patient failed to respond well immediately after operation. Cardiac decompensation and progressive renal insufficiency manifested by oliguria and uremia developed. The patient died from a high fever apparently caused by terminal bronchopneumonia 5 days after operation. Permission for necropsy was not granted. It was our impression that the oliguria was secondary to cardiovascular collapse.

The daily urinary output for the immediate postoperative days in those patients in whom the value of plasma hemoglobin was more than 500 milligrams is given in Table VI.

Studies of serum bilirubin were performed postoperatively in a small number of cases in which the higher levels of plasma hemoglobin were present. As expected the van den Bergh reaction was indirect in each and the concentration of serum bilirubin was mildly elevated.

COMMENT

The incidence of hemolysis following transurethral resection in this series (56 per cent) compares favorably with that in similar series reported by others. Creevy found postoperative hemolysis in 19 of 27 cases (70 per cent) in which water was employed for irrigation at the time of resection. Landsteiner and Finch also reported hemolysis after 10 of 15 trans-

urethral prostatic resections (66 per cent). Undoubtedly if our criterion for hemolysis had been a concentration of hemoglobin of more than 5 milligrams per 100 cubic centimeters of plasma instead of 25 milligrams our results would approximate those of others even more closely.

We have shown that the operative loss of blood, the weight of tissue removed and the technical difficulty of resection all tend to be greater in cases in which the postoperative concentration of plasma hemoglobin is increased. Creevy has shown that irrigating fluid composed of 4 per cent glucose may wash into the blood stream during resection to such an extent that the postoperative level of blood sugar may rise to more than 1,000 milligrams per 100 cubic centimeters. Similarly Landsteiner and Finch labeled irrigating fluid used during transurethral resection with known quantities of sodium salicylate. They found a high concentration of sodium salicylate in the blood of a patient who also had a high concentration of plasma hemoglobin after resection and calculated that about 1,000 cubic centimeters of irrigating solution had washed into the blood stream during the procedure. That distilled water may cause hemolysis when injected intravenously has been shown by Krumbhaar on dogs and by Landsteiner and Finch on human beings. Therefore it is reasonable to assume that when large amounts of tissue are resected when excessive bleeding occurs, or when the resection is difficult, large amounts of irrigating fluid may wash into the circulation through venous sinuses in the prostatic bed and may induce hemolysis.

Our study of postoperative reactions secondary to accumulation of plasma hemoglobin following transurethral prostatic resection appears to show that gastrointestinal complaints are more frequent in patients with hemolysis. Of the patients with concentrations of hemoglobin of more than 200 milligrams per 100 cubic centimeters of plasma, approximately 85 per cent complained of postoperative nausea, vomiting or anorexia, whereas approximately 45 per cent of those with concentrations of less than 100 milligrams had such complaints. In other words, postoperative gastrointestinal symptoms occurred twice as

frequently in patients with high concentrations of plasma hemoglobin as in those with no significant hemolysis. Such a result coincides with observations made after the experimental injection of hemoglobin into human beings.

The results from our study of postoperative fever and chills are not consistent with past observations. The experimental injection of large doses of hemoglobin into human beings apparently causes fever and chill at times. Also the febrile reaction accompanying such clinical syndromes as the hemolytic reaction following transfusion with incompatible blood is well known. Yet we found chills in neither the group of cases with hemolysis nor in the cases without hemolysis and fever occurred in a higher percentage of cases without hemolysis than in those with significant hemolysis. The many factors causing febrile reactions following transurethral prostatic resection undoubtedly account for this discrepancy.

The patient in this series who had postoperative oliguria did not have significant hemoglobinemia following resection. This does not prove that hemoglobinemia does not induce oliguria. It has been stated previously that postoperative oliguria is based on many factors of which hemoglobinemia may be only one. Actually the levels of plasma hemoglobin reported in the literature to induce renal insufficiency are higher than the concentrations in the cases in our series. In dogs Flink injected sufficient hemoglobin to produce concentrations of at least 3 700 milligrams of hemoglobin per 100 cubic centimeters of plasma before renal insufficiency developed. In human beings there is evidence to indicate that the same high levels of plasma hemoglobin are necessary before renal insufficiency develops. Comparison is difficult however because many of the published reports concerning the development of renal insufficiency following hemoglobinuria either fail to give the level of plasma hemoglobin at its height prior to the onset of oliguria or do not mention the time interval between the onset of hemoglobinuria and the determination of plasma hemoglobin. We have previously stated that hemoglobin is rapidly removed from the blood stream yet Altschule and Gilligan found the plasma hemoglobin to be 500 milligrams per 100 cubic

centimeters 24 hours after the onset of hemoglobinuria in a patient in whom the concentration of nonprotein nitrogen rose to 90 milligrams per 100 cubic centimeters of blood but who recovered. Fox and Ottenberg described 4 cases of hemolytic anemia and hemoglobinuria due to sulfonamides in which the hemoglobin content of the plasma ranged from 400 to 1 700 milligrams per 100 cubic centimeters. Two patients died from renal insufficiency but the time interval between onset of hemolysis and determination of the level of plasma hemoglobin varied between 12 and 48 hours. Fairley and Bromfield observed 3 patients who died of anuria from blackwater fever the concentrations of plasma hemoglobin were 3 600 4 610 and 5 140 milligrams per 100 cubic centimeters. By way of contrast with these figures only 6 of the 100 patients in our series had more than 500 milligrams of hemoglobin per 100 cubic centimeters of plasma immediately after resection of these 1 had a level of approximately 1 000 milligrams. This could indicate that concentrations of plasma hemoglobin commonly attained during transurethral prostatic resection are not sufficiently high to cause renal insufficiency. However Creery has advanced the opinion that in order to produce renal insufficiency in elderly men who have lost blood while under anesthesia high values of plasma hemoglobin may not be necessary.

SUMMARY AND CONCLUSIONS

Some fundamental concepts of hemoglobinemia and hemoglobinuria were reviewed to interpret the results of a study of plasma hemoglobin in 100 cases of transurethral prostatic resection performed at the Mayo Clinic.

The incidence of hemoglobinemia following transurethral resection in this series was 56 per cent. This incidence is somewhat lower than that previously reported perhaps because our criterion for hemoglobinemia was based on a higher concentration of plasma hemoglobin than others have employed. Factors during resection which accompanied or may have predisposed to postresection hemoglobinemia in this series were the weight of tissue resected volume of operative blood lost and the difficulty of resection.

Postoperative gastrointestinal symptoms were more common among those patients of this series who had high concentrations of plasma hemoglobin than among those who did not have any hemolysis. Hemolysis did not appear to increase the incidence of postoperative fever and chills in this series.

Concentrations of plasma hemoglobin per se commonly attained during transurethral prostatic resection usually are not sufficiently high to produce anemia.

PHYSIOLOGIC METHODS IN THE DIAGNOSIS OF CONGENITAL HEART DISEASE

THE introduction of surgical procedures for the correction of congenital malformations of the heart and great vessels by Blalock, Craford and Gross and their associates has placed emphasis on the correct preoperative diagnosis of these lesions. A great many of these malformations can be correctly diagnosed by fluoroscopic and physical examination. In borderline cases however more elaborate procedures are necessary. These include visualization of the heart and great vessels with radio-opaque material (angiocardiography) and physiological procedures.

The most useful physiological studies are catheterization of the heart, measurement of pulmonary capillary flow, a standard exercise test and oximetry.

Venous catheterization of the heart is of particular value. The fullest amount of information is obtained if three criteria are fol-

lowed: (1) The position of the catheter should be closely followed under the fluoroscope. (2) Blood samples and pressures should be obtained by means of the catheter from the cardiac cavities, from blood vessels coursing to and from the heart, and from a peripheral artery. The oxygen content of these samples should be determined. Pressures should be recorded with differential manometers. The measurement of mean pressures with saline or mercury manometers does not give sufficient information, since the height of the diastolic pressure is frequently of particular diagnostic importance. (3) The volume of blood flowing through the pulmonary artery (pulmonary artery flow), the intracardiac shunt and the systemic vessels (systemic blood flow) should be calculated by the Fick principle from the oxygen content of the blood samples. The main diagnostic value of these calculations lies in the recognition of reduced pulmonary artery flow and in the estimation of the volume and the direction of the intracardiac shunt. Of particular importance is the calculation of the effective pulmonary blood flow. This represents the amount of mixed venous blood which reaches the pulmonary alveoli. The ratio of the effective pulmonary blood flow to the total systemic flow determines the degree of oxygen saturation in arterial blood. The Blalock-Taussig operation is beneficial because this ratio is increased through the construction of an artificial ductus.

In the surgical laboratory of the Johns Hopkins Hospital catheterization of the heart has now been performed on approximately eight hundred individuals with congenital heart disease. In five of these air emboli to the brain occurred during the catheterization.

However all symptoms disappeared within 24 hours and there was no residual damage.

The pulmonary capillary flow is determined by a method involving the equilibration of carbon dioxide with pulmonary capillary blood the sampling of carbon dioxide content in alveolar air and the determination of carbon dioxide production. While sampling of pulmonary artery blood permits the calculation of the pulmonary artery flow only the carbon dioxide equilibration method measures the total amount of blood perfusing the lungs (pulmonary capillary flow). By comparing pulmonary artery with pulmonary capillary flow the flow through the collateral vessels or through an artificial or congenital ductus arteriosus may be estimated.

The standard exercise test compares the ratios of the oxygen consumption to respiratory minute volume during a standard exercise test and at rest. Normally the oxygen consumed per liters of ventilation increases from rest to exercise. In conditions in which pulmonary flow is fixed (e.g. pulmonary stenosis) this ratio usually declines. The test is easily performed and requires no special preparation.

The oximeter is an instrument which measures the oxygen saturation in peripheral arterial blood by means of a photoelectric cell attached to the pinna of the ear. The original Millikan instrument has been greatly improved by the more accurate models designed by Woods and Geraci and by R. T. Cox. The newer models permit the measurement of the arterial oxygen saturation within 5 per cent accuracy. The fact that the peripheral oxygen saturation falls during exercise in the presence of a venous arterial shunt can be demonstrated with great ease by oximetry. This is usually carried out simultaneously with the standard exercise test. Furthermore, the oximeter is useful in differentiating anoxemia due to ve-

nous-arterial shunts from arterial unsaturation due to oxygen transfer difficulties resulting from pulmonary disease. In the latter case the oxygen saturation rises within one minute to full saturation when 100 per cent oxygen is inhaled. In the presence of a venous-arterial shunt on the other hand the rise in oxygen saturation will extend over several minutes and full arterial oxygen saturation is rarely obtained.

The results of these tests in tetralogy of Fallot show a decrease in pulmonary artery flow an intracardiac shunt predominantly directed from right to left and usually evidence of marked collateral circulation to the lung. The systolic pressure in the right ventricle is significantly elevated above that in the pulmonary artery. The exercise test shows a fall in the oxygen consumed per liters of ventilation and a decline in the peripheral arterial oxygen saturation. On the breathing of pure oxygen the peripheral arterial oxygen saturation rises over a period of several minutes and full saturation is not reached.

In Eisenmenger's complex and in a great majority of auricular or ventricular septal defects the pulmonary artery pressure is elevated. This is probably the result of arteriolar changes in the pulmonary vessels. As a result of the increased resistance in the pulmonary vascular bed the overall direction of the intracardiac shunt may be from right to left.

Elevation of the pulmonary artery pressure due to increased resistance in the pulmonary bed is also frequently encountered in auricular or ventricular septal defects. In the presence of an auricular septal defect the oxygen content of right auricular blood exceeds that of vena caval blood. With a ventricular septal defect the oxygen content of right ventricular blood exceeds that of right auricular blood. During the standard exercise test the oxygen consumed per liters of ventilation usually in

creases and the oxygen saturation of peripheral arterial blood falls

Recent advances in the surgical treatment of transposition of the great vessels by Blalock and his associates have focused the interest of pediatricians and surgeons on this malformation. The intracardiac hemodynamics in transposition of the great vessels differ from those described for the tetralogy of Fallot and related conditions. In transposition the pulmonary arterial blood flows from the left ventricle through the lungs into the left auricle while the systemic blood courses from the right ventricle into the aorta through the systemic circulation and back into the right auricle. If this malformation is to be compatible with life, oxygenated blood must reach the aorta either through a septal defect or a patent ductus arteriosus. However, the volume of oxygenated blood shunted into the systemic circulation must be balanced by an equal volume of unsaturated blood entering the pulmonary circulation, since a unilateral shunt would lead rapidly to a diminishing blood volume in either the pulmonary or the systemic circulation. The volume of the shunted blood in either direction equals the effective pulmonary blood flow. The practical importance of these considerations lies in the fact that any surgical correction of transposition which involves the creation of a unilateral shunt must be balanced by an equal and opposite shunt.

In patent ductus arteriosus the blood oxygen content in the pulmonary artery exceeds that in the right ventricle. The blood pressure in the pulmonary artery may be normal or slightly elevated. The oxygen consumed per liters of ventilation and the oxygen saturation in peripheral arterial blood remain constant during the standard exercise test.

The physiological procedures described are of particular value in the recognition of diminished pulmonary artery flow and of de-

creased or increased pulmonary arterial pressures. In most instances they are helpful in identifying and locating intracardiac or extracardiac shunts. Furthermore, changes in hemodynamics produced by operative procedures can be quantitatively evaluated. As the field of cardiac surgery expands into the realm of acquired heart disease, physiological studies will be of increasing importance in supplying the surgeon with essential criteria for operative intervention.

RICHARD J. BING

EXSTROPHY OF THE BLADDER

EXSTROPHY of the bladder is one of the rare congenital anomalies occurring once in 40,000 births, which is amenable to surgical treatment, but the fact that there have been about seventy different surgical procedures described for its correction indicates that there must be many points of interest about the technique and results of the surgical methods which remain unsatisfactory.

The optimal time for operation is one of the points for discussion. When one considers that from a statistical point of view half of these patients are dead by their tenth year and two-thirds are dead by their twentieth year, it simply indicates that whatever is done for them must be carried out before adolescence and more particularly before the tenth year. In recent years it has been recommended that these operations be done during the first twelve months of the patient's life under the supposition that an infant tolerates trauma unusually well and that the anomaly should be corrected before any recurrent renal infection develops. In evaluating this point one should remember that perhaps it is better to delay until the patient has learned bowel control. Also this condition is not considered a surgical emergency as is pyloric stenosis, tracheobronchial fistula, strangulated umbili-

cal hernias, and so forth so that one can conceivably wait until the fourth or fifth year when the anatomic structures are larger and anastomosis can be more satisfactorily and accurately done. The preparation of the bowel for ureterosigmoidal anastomosis can also be done more easily and completely. Since the results depend almost entirely on the character of the anastomosis, these structures should be of such size as will enable one to approximate them accurately without tension. I doubt if these conditions which are so vital to the conduct of the operation and to the future health of the patient are present before the patient is five years of age.

Bilateral ureterosigmoidal anastomosis and cystectomy are regarded as the proper procedures for surgical correction of exstrophy of the bladder to be followed by any plastic procedures which may be required on the external genitalia of either sex. Whether this ureteral transplantation should be done in one stage or two stages has been a matter of considerable debate. The decision depends it would seem on the type of anastomosis which is used and on the fact that antibiotics and penicillin are available in the preparation of the sigmoid and for the prevention of postoperative infection of the urinary tract. In earlier years a two stage operation either extraperitoneal or intraperitoneal was generally regarded as the proper procedure. More recently with improvement in the technical procedures of the anastomosis and in preparation of the bowel the one stage operation is favored.

The object of the operation is to secure an adequate urinary sinus between each ureter and the sigmoid without subsequent ureteral obstruction or retrograde contamination of the upper part of the urinary tract. It is on account of these two factors particularly that many operations have been devised direct to the improvement of the ureterosigmoidal

anastomosis. Obviously the anastomosis can be more perfectly and accurately accomplished by the transperitoneal approach because to carry out this procedure it is vital that the sigmoid be accurately placed adjacent to the ureter on each side and that the ureter be placed in the bowel without tension and without fixation. When tension and fixation of the ureter occur at the point of union to the bowel there will be interference with its delicate blood supply and the incidence of ureteral fistula increases. Also the rhythmic contraction of the ureter for the proper expulsion of the urine into the bowel will not be normal and there will be subsequent obstruction and ureteral dilatation with infection of the urinary tract. Under these circumstances then the most favorable situation is where the ureter is placed within the bowel devoid of any sutures catheters or guides. This can be accomplished by the standard Coffey Mayo technique with these exceptions the ureter is gently pulled into the bowel for a distance of 3 to 4 centimeters and is held firmly until the bowel can be fixed to the parietal peritoneum for a distance of at least 4 centimeters above and below the point where the ureter enters the wall of the sigmoid. The bowel is fixed firmly to the peritoneum so that the ureter goes directly into the bowel without tension or any fixation. The peritoneum if properly placed with relation to the bowel will close any defect in the bowel within a few hours and will prevent any leakage of urine or intestinal contents.

Patients who have practically normal pyelograms and ureterograms within a few months subsequent to transplantation rarely have any attacks of infection of the upper part of the urinary tract a fact which must indicate that the surgical procedure which was utilized approached at least the desired requirements. Further evidence that delayed urinary complications are directly attributable to the character of the anastomosis is shown by the fact that if a kidney becomes functionless the left one is involved three times more commonly than the right kidney and the correct application of the sigmoid to the peritoneum on the left side without tension on the ureter is three times more difficult to accomplish than on the right side.

Obviously then the surgical problem in managing exstrophy of the bladder is to select the favorable time for surgical intervention to give strict attention to securing a uretero-sigmoidal anastomosis without tension or fixation of the ureter and to require periodic studies of the upper part of the urinary tract of the postoperative patients for from three to five years.

If in a few months or years ureteral obstruction appears and becomes progressive with a gradual loss of renal function permanent nephrostomy or ureterostomy is the operation of choice and will add a number of years to the patient's life expectancy.

A good functioning skin ureterostomy is more serviceable to the patient than a nephrostomy because the patient can change the catheters himself when necessary and can adjust them to the proper level within the renal pelvis to obtain efficient drainage. A catheter which does not extend to the renal pelvis will have urine leaking around it.

Good skin ureterostomies are difficult to produce and this procedure should not be

undertaken by anyone who is not familiar with the conditions which may arise that will cause complete failure of the operation such as sloughing and retraction of the end of the ureter below the abdominal wall pressure from the catheter or an abscess in the wall of the ureter may produce a ureteral fistula thereby ruining the operation.

A nephrostomy is a less complicated procedure and can be done subsequently if a skin ureterostomy has for any reason been a failure. It is more troublesome to the patient because some one must change the nephrostomy tubes and dress the area for him. A nephrostomy is practically a defect proof operation and can be performed by most surgeons interested in this field of surgery. Even so I feel it should be emphasized that to secure a good functioning nephrostomy it should be so placed that it goes directly down from the skin surface through the kidney and into its pelvis. Should the pelvis be a bifid one or should there be a complete duplication then double nephrostomies may be necessary but such information must be available before the operation is begun.

These two surgical procedures should be considered as a reserve which may be utilized subsequently to prolong the life and comfort of patients if for any reason the ureterosigmoidostomy has become defective with consequent destruction of renal tissue and function.

The use of antibiotics and penicillin during preparation for and subsequently to surgical treatment will increase life expectancy to a considerable degree. Certainly the future for these patients is promising especially when one considers that without these drugs 50 per cent of patients were alive twenty five to thirty years after operation.

VIRIL S. COUNSELLER

cal hernias, and so forth so that one can conceivably wait until the fourth or fifth year when the anatomic structures are larger and anastomosis can be more satisfactorily and accurately done. The preparation of the bowel for ureterosigmoidal anastomosis can also be done more easily and completely. Since the results depend almost entirely on the character of the anastomosis, these structures should be of such size as will enable one to approximate them accurately without tension. I doubt if these conditions, which are so vital to the conduct of the operation and to the future health of the patient are present before the patient is five years of age.

Bilateral ureterosigmoidal anastomosis and cystectomy are regarded as the proper procedures for surgical correction of exstrophy of the bladder to be followed by any plastic procedures which may be required on the external genitalia of either sex. Whether this ureteral transplantation should be done in one stage or two stages has been a matter of considerable debate. The decision depends it would seem on the type of anastomosis which is used and on the fact that antibiotics and penicillin are available in the preparation of the sigmoid and for the prevention of postoperative infection of the urinary tract. In earlier years a two stage operation either extraperitoneal or intraperitoneal was generally regarded as the proper procedure. More recently with improvement in the technical procedures of the anastomosis and in preparation of the bowel the one stage operation is favored.

The object of the operation is to secure an adequate urinary sinus between each ureter and the sigmoid without subsequent ureteral obstruction or retrograde contamination of the upper part of the urinary tract. It is on account of these two factors particularly that so many operations have been devised directed at the improvement of the ureterosigmoidal

anastomosis. Obviously the anastomosis can be more perfectly and accurately accomplished by the transperitoneal approach because to carry out this procedure it is vital that the sigmoid be accurately placed adjacent to the ureter on each side and that the ureter be placed in the bowel without tension and without fixation. When tension and fixation of the ureter occur at the point of union to the bowel there will be interference with its delicate blood supply and the incidence of ureteral fistula increases. Also the rhythmic contraction of the ureter for the proper expulsion of the urine into the bowel will not be normal and there will be subsequent obstruction and ureteral dilatation with infection of the urinary tract. Under these circumstances then the most favorable situation is where the ureter is placed within the bowel devoid of any sutures, catheters or guides. This can be accomplished by the standard Coffey Mayo technique with these exceptions the ureter is gently pulled into the bowel for a distance of 3 to 4 centimeters and is held firmly until the bowel can be fixed to the parietal peritoneum for a distance of at least 4 centimeters above and below the point where the ureter enters the wall of the sigmoid. The bowel is fixed firmly to the peritoneum so that the ureter goes directly into the bowel without tension or any fixation. The peritoneum if properly placed with relation to the bowel will close any defect in the bowel within a few hours and will prevent any leakage of urine or intestinal contents.

When one reviews the deaths after ureterosigmoidostomy for exstrophy it is noted that 50 per cent of the deaths in the hospital are due to pyelonephritis, ureteritis with or without gangrene and peritonitis and that uremia and pyelonephritis with stones or hydronephrosis or both account for 65 per cent of the deaths after the patients leave the hospital.

THE GENTLEMAN FROM TENNESSEE

FRANCES TOMLINSON GARDNER, San Francisco, California

ANDREW JACKSON is a legend. His political career, his army life, and his domestic career have been explored as thoroughly as the personal affairs of Hamlet's father. His biographers, although they have meticulously recorded all these things, have touched on the subject of his health and physique with the small interest of casual reporters. Andrew Jackson was made of the usual blood and bone but the one was thin and the other fragile. No structure ever endured under greater handicaps than the frame that supported the brain of the astonishingly determined, the invincible gentleman from Tennessee.

He was normally born to sturdy pioneer parents in the Waxhaws Settlement of North Carolina in March 1767. His father was recently dead of an injury resulting from trying to lift a fallen tree single handed. His energetic mother died of typhus when Andrew was fifteen. His two brothers were robust and died of causes unrelated to heredity. In Andy's early youth his only recorded skirmish with disease was an attack of something called "The Big Itch" of which it was said that it itched one very much all over.

His small taste of the Revolutionary War ended in his capture by the British who imprisoned the boy and his brother Robert in a blockhouse near Camden. Due to a refusal to black the boots of a demanding British officer Andrew received the saber cuts on wrist and temple which were still prominent when the old man died sixty-four years later. Hidden but of far deeper significance was the rancor which settled in the inner Jackson and which colored every thought and action toward the British most of the days of his life.

Still in bandages from the assault, he as well as his brother caught the smallpox which swept the unhygienic quarters in which they were housed. News of the epidemic reached Mrs. Jackson and he came to prevail upon the British to release the

presumably dying children to her custody so that he could take them home to nurse them. The British gladly consented since for them it meant two invalids less and Mrs. Jackson loaded Robert the sicker of the two on her only available horse Andrew horseless and hardly less ill walked the entire forty miles back to the cabin in the Waxhaws. Robert did not live to get home and Andrew soaked by a pouring rain and with his smallpox driven in arrived in a raging fever and delirium. To everyone's surprise he eventually recovered and no one paid much attention to the long siege of fever and ague which he endured after the disease had subsided. From this time began the underscoring of low fever, intermittent fever or fever which was seldom absent from Jackson's own mention of his health. In the fastnesses of North Carolina malaria was endemic. Who was he to escape?

At fifteen he was long, skinny and sallow. His manners were bad and his language deplorable. While he was at school though he was as thin as a pencil and as fragile as a pipestem he would fight at the drop of an epithet anyone who had the misfortune to annoy him. He seldom won since everybody else was stronger and heavier but it was not important to him. Nor was it important that the same boy might have beaten him unmercifully the day before. He learned very young that offense was his best defense and through it he did manage at considerable physical expense to keep at a minimum unkind comment about his embarrassing physical defect. It must be admitted that from infancy to manhood poor Andrew was a drooler. The condition was bad enough when he was calm but when he became excited it was gushingly profuse. Since he could not swallow fast enough to dispose of the quantities of saliva with which his overactive parasympathetic nervous system afflicted him, he could only defend his right to it. Since it was a vicious circle he spent much of his time in a sort of frenetic bellicosity.

ANDREW JACKSON is a legend. His political career, his army life, and his domestic career have been explored as thoroughly as the personal affairs of Hamlet's father. His biographers, although they have meticulously recorded all these things, have touched on the subject of his health and physique with the small interest of casual reporters. Andrew Jackson was made of the usual blood and bone, but the one was thin and the other fragile. No structure ever endured under greater handicaps than the frame that supported the brain of the astonishingly determined, the invincible gentleman from Tennessee.

He was normally born to sturdy pioneer parents in the Waxhaws Settlement of North Carolina in March 1767. His father was recently dead of an injury resulting from trying to lift a fallen tree single-handed. His energetic mother died of typhus when Andrew was fifteen. His two brothers were robust and died of causes unrelated to heredity. In Andy's early youth his only recorded skirmish with disease was an attack of something called The Big Itch, of which it was said that it itched one very much all over.

His small taste of the Revolutionary War ended in his capture by the British who imprisoned the boy and his brother Robert in a blockhouse near Camden. Due to a refusal to black the boots of a demanding British officer, Andrew received the saber cuts on wrist and temple which were still prominent when the old man died sixty-four years later. Hidden but of far deeper significance was the rancor which settled in the inner Jackson and which colored every thought and action toward the British most of the days of his life.

Still in bandages from the assault, he, as well as his brother, caught the smallpox which swept the unhygienic quarters in which they were housed. News of the epidemic reached Mrs. Jackson and he came to prevail upon the British to release the

presumably dying children to her custody so that she could take them home to nurse them. The British gladly consented since for them it meant two invalids less, and Mrs. Jackson loaded Robert, the sicker of the two, on her only available horse. Andrew, horseless, and hardly less ill, walked the entire forty miles back to the cabin in the Waxhaws. Robert did not live to get home and Andrew, soaked by a pouring rain and with his smallpox driven in, arrived in a raging fever and delirium. To everyone's surprise he eventually recovered and no one paid much attention to the long siege of fever and ague which he endured after the disease had subsided. From this time began the underscoring of low fever, intermittent fever, or fever which was seldom absent from Jackson's own mention of his health. In the fastnesses of North Carolina malaria was endemic. Who was he to escape?

At fifteen he was long, skinny, and sallow. His manners were bad and his language deplorable. While he was at school, though he was as thin as a pencil and as fragile as a pipestem, he would fight at the drop of an epithet anyone who had the misfortune to annoy him. He seldom won since everybody else was stronger and heavier, but it was not important to him. Nor was it important that the same boy might have beaten him unmercifully the day before. He learned very young that offense was his best defense and through it he did manage at considerable physical expense to keep at a minimum unkind comment about his embarrassing physical defect. It must be admitted that from infancy to manhood poor Andrew was a drooler. The condition was bad enough when he was calm but when he became excited it was gushingly profuse. Since he could not swallow fast enough to dispose of the quantities of saliva with which his overactive parasympathetic nervous system afflicted him, he could only defend his right to it. Since it was a vicious circle, he spent much of his time in a sort of frenetic bellicosity.

The fortunate demise of a rich uncle in Carrickfergus, Ireland put the gangling adolescent in possession of several hundred pounds. With these he bought himself a horse and some good clothes and set off to improve his education and neck his fortune. After a short stay in Charlotte he descended with a flourish upon Salisbury where he cut a handsome swath. He was developing what his detractors, in these and later years, called his other manners—the polished ones. In pursuing the polish he left his money far behind and after a year departed from Salisbury financially a ruin.

This short study of money and manners convinced Andrew that success would crown only greater effort and real concentration. He abandoned his wild oats in midfield and, after two years of determined study, passed his examinations and became prosecutor in the court of Judge John McNairy in Nashville. He was only twenty-one which would seem callow for a prosecutor had it not been that the judge was only twenty-six. Andrew's courtroom manner was still a moderately adult application of his childhood aggressiveness, but since it was usually backed by evidence, it began to help instead of hinder.

Andrew boarded with the family of John Donelson where he met Rachel Donelson Robards, estranged from her disreputable husband and living in her father's house. The love of Andrew and Rachel was a crucial factor for it like the inner damage inflicted by the attack of the British officer colored every action of his life thereafter. In this woman's defense he received wounds which determined the course of his health and, because of her, he nearly failed to win the presidency.

Robards, drunk but determined, used threats and ruses to force the return of his wife. None of the moments of best romantic tradition were slighted in the course of the affair. In 1790, worn out by the struggle, Rachel did return to her begging husband but found life so unendurable that she sent for someone to come and take her away again. Her family sent Jackson. Like the knight in shining armor he swept her away to her sister. It was an innocent voyage of desperation but it might as well have been the blackest of elopements. Rachel's reputation tottered.

Robards declared that he would sue for divorce immediately and, presumably, went off to do so. Hearing no more Jackson and Rachel waited a proper length of time and then in 1791 were quietly married. It is odd that Jackson, with his legal training, did not bother to make sure that all obstacles had been removed and that Rachel was a free if sullied character. He made a grave mis-

take because Rachel was not free. Her disgruntled and cunning husband had never divorced her at all. He had only gone so far as to procure an "enabling act" which gave him the right to petition, but was nothing more in itself. So, to the crime of having run away with another man's wife, Andrew Jackson added the sin of living with her for three years without benefit of marriage. In 1794 Robards tired of the game and put the divorce through. By this time our red-headed friend had become so stubborn and righteous that he had to be strongly persuaded that, for the benefit of anything that remained of Rachel's reputation, it was necessary to remarry her. After much display of Jacksonian temper and some speeches about the eyes of God, the pair went through another ceremony. Unfortunately by this time, no act of his could repair the damage to Rachel's good name. For thirty-seven years her husband defended her valiantly but hopelessly. In honor of what he called "The Sacred Name" he used whips, fists, and pistols on calumniators but he was never able to restore her to respectability. When he was made president the poor little woman did her best to prepare for what must have loomed to her as a hideous and endless ordeal. By the grace of some kind of Providence on the eve of her departure for Washington, a final heart attack stepped in, and Jackson entered the White House a widower.

In 1806 ill feeling of some years standing came to a climax when Charles Dickinson publicly slurried the name of Rachel Jackson. The conduct of the resulting duel has been discussed acrimoniously for the past hundred and forty two years, not always to the credit of Jackson, the survivor. He appeared on the field in an enormous black overcoat, which he did not remove. He was so thin that the bulk of the coat effectively disguised all the landmarks by which a duellist works and Mr. Jackson's heart was not where Mr. Dickinson had every reason to believe it belonged. Consequently the well-aimed bullet went wide of the mark, tore the chest muscles, broke a rib or two and settled in the chest cavity where it remained the rest of Jackson's life. Dickinson having shot was thus disarmed and forced by honor to stand still while Jackson, bleeding but not dead as he should be, took careful aim and shot him in the stomach. Dickinson died in agony some hours later. Jackson, after some histrionic nonchalance about his injuries, finally allowed himself to be examined and put to bed. It was then found that the wound was more severe than he had thought. He was more than a month in getting around again.

Through the years until 1813 when he was forty-six run these recurrent comments growing gradually more frequent "I have had a severe attack of fever a cold with pain in the breast and a cough" "Severe attack of dysentery serious intermittent fever and by the turn of the century rheumatism especially in the right arm. He was never well but in his own opinion he was never very ill. These were his years of growth politically militarily and in his private life. A twentieth century man faced with the symptoms which were beginning to appear in Andrew Jackson would withdraw from the world and retire with misgivings to a little white cot in the sun but Jackson lived with different opinions about health and in a glorious ignorance.

Several of his biographers including Parton claim that the effects of the Dickinson duel were largely responsible for the death of the old gentleman thirty nine years later. Inasmuch as the bullet lay within his chest cavity during all these years and since the picture of his final dissolution is not one of terminal tuberculosis at all but of a combination of other things, they were right in a sense though wrong in their major premise which was to the effect that the bullet agitated into flame the latent tuberculosis in the Jackson chest. It is doubtful on the contrary if Jackson ever had tuberculosis at all. True he had occasionally complained of cough and a pain in his chest but always after serious exposure as when he appeared at a midnight fire on a cold wet night without his coat or shirt. A homely diagnosis of bronchitis sounds appropriate here. The recurrent fever is accounted for by his malaria and his dysentery by the ubiquitous ameba or bacillus. The emaciation and poor color would hardly be unexpected in a body struggling against all these afflictions.

Parton claims that a fall in 1825 tore open the wound of the Dickinson duel and re-established the process of degeneration. This statement presupposes that in the interval there had been an improvement. This was not true. There was only a slow but definite decline. It is true that in 1825 Jackson did fall heavily and that the immediate consequence was profuse pulmonary hemorrhage but Parton and the others in their preoccupation with the Dickinson duel neglect to weigh other factors which became evident during the intervening years. By 1825 the sting of a bee was enough to upset the invalid.

When the bullet entered his thoracic cage and lodged there it carried with it bits of cloth dust particles and other foreign matter. Just where the bullet went is a moot question for there was no x ray machine. Perhaps it lay beside his heart

perhaps it impinged on his left lung. Whatever it did it immediately set up an inflammatory process and promoted an abscess nearby. Meanwhile the torn musculature of the shoulder predisposed the bruised underlying tissue to infection. There is every inducement and no deterrent to the formation of a pulmonary abscess.

In the early years of the nineteenth century with its incomplete knowledge of respiratory disease nearly anything which produced cough sputum bleeding and wasting was tuberculosis. The great strides of the nineteenth century were barely beginning and the complicated reaction of the body tissue to disease superimposed upon disease was far beyond the most informed of contemporary physicians. Jackson developed all the classic signs of tuberculosis, ergo he was tuberculous. This was excellent reasoning but it did not go far enough. In all probability the man was becoming the victim of a series of unlucky illnesses any of which was formidable and which all together unhealed and unintelligently treated lead inevitably to that dogged murderous follower of long standing suppuration—amyloid disease.

In 1813 through the unfortunate championship of the wrong man in another duel Jackson became involved in what developed into a tavern brawl. His one-time good friends Thomas and Jesse Benton and assorted other people met with Jackson and his friends and indulged in a battle which involved fists clubs and pistols. Jackson was shot twice by Jesse Benton once in the already damaged left shoulder and again just below it in the left arm. There was no sauntering around this time. The weak shoulder was shattered and the second bullet did not emerge from the arm. It lay against the bone in the heavy muscle and it had like its predecessor in the chest introduced its contribution of cloth and dust particles. The hemorrhage was so massive that two mattresses belonging to the Nashville Inn were rendered useless for any future guest before it could be brought under control. Surrounded by all the doctors in Nashville all but one of whom urged amputation Jackson whispered "I'll keep the arm." He allowed poulticing with slippery elm and transplanted to the Hermitage he stayed in bed for three weeks simply because he was too weak to get up. This was not the end of that wound. The arm was in a sling for six months. Never until the bullet was removed nineteen years later did the inflammation subside. During all this time an active osteomyelitis was in progress.

While he lay coughing and sweating and aching the affairs of the nation went on. The Creek In

hans rose in revolt. When the report was brought to Nashville it had the anticipated effect upon the prostrate warrior. With undeniable heroism and appalling fortitude he hauled himself on his horse and went off to subdue the rebels. He could have been little better than a bedridden ruin. His shoulder was unhealed, his arm was useless and his temperature must have been prostrating since he was also in the muddle of a severe attack of dysentery. Dr. Frederick May, who accompanied him, was asked on his return how the general had survived the trip. Dr. May's interesting but somewhat cryptic reply was that they had had to stop frequently and wash the general all over with sugar of lead to keep down the inflammation.

Sugar of lead believed at the time to have some peculiar antiphlogistic action beyond its simple astringent powers, was Jackson's great support. He used it not only internally for his supposed tuberculosis and his chronically queasy stomach but externally for anything that bothered him. He even used it as an eye wash when his sight began to fail. Since his specific for his dysentery was calomel which he took in massive doses it raises the question whether after years of constant use some of his various life efforts might not have been increased by a touch of lead or mercury poisoning. The only other drug that he would countenance was common salt for emergency use in pulmonary hemorrhage which he backed up with the free and effective use of the lancet.

Within a few days of his war arrival was fought the battle of Tellico. One of the critical battles of the Creek War. Jackson was so ill that he could neither lie comfortably nor sit. During the paroxysms of his dysentery he propped himself in some strange manner over two poles, from which he hung hour after hour. This brings up an interesting point since a shoulder badly wounded as his recently had been would not have been in much of a condition to use as a support. By what portion of his anatomy was Jackson for several days supported? To his misery was added the lack of food since a complete breakdown of the service of supply had thrown the army on the scanty resources of an empty terrain. Jackson, racked with dysentery, subsisted on raw acorns and some of the entrails of an unfortunate hog.

Incredible man. Through the whole of this campaign and that which followed and ended with the Battle of New Orleans, his suffering and his endurance were beyond belief. In Mobile the wounded arm sloughed a piece of necrotic bone which he lovingly sent to Rachel. There was hardly a moment when he was not racked with fever, nauseated and in harsh pain. Yet if ne-

cessity demanded he would descend from the horse on which he seemed barely able to sit and march or fight beside his men until the emergency was over. It was these years which earned him the name "Old Hickory."

He arrived in New Orleans late in 1814, hailed as the country's hero. He had come to defend the city against the British attack which was momentarily expected. The citizens were beside themselves with enthusiasm for him and prepared a welcoming breakfast in the succulent manner of the best creole cooks. When he arrived he was, as usual, just recovering from a serious bout of fever and was gaunt, grey, unshaven, and disheveled. He was also very cranky and his stomach was so squeamish that confronted with all the culinary wonders of New Orleans he ate a tablespoonful of hominy and a little milk. Disappointed to tears, the hostess of the occasion spoke with apertly about the ugly old haintuck flat-boatman who was shuffling around the beautiful floor in his muddy boot. What a catastrophe was the general.

New Orleans was shocked to its suave core but it was game. Its leaders, realizing that battles were not won with company manners, gave him the co-operation needed during the days before the battle. Mr. Livingston, a local *akle de camp* determined to obey the social amenities in the face of outrage, summoned influential New Orleans to a dinner in his honor. New Orleans came with misgivings, but it came. Uneasily it sat awaiting the arrival of its celebrated incubus. The door opened. Surrounded by his aides in marched a slender, bronzed, superbly erect gentleman whose well brushed hair framed a quizzical but smiling—and shaven face. His uniform was pressed and brushed. His high boots gleamed. His sword gleamed as a sword should do. His voice was soft and his conversation impeccable. New Orleans fell at his feet in relieved embarrassment. Now, oh what a joy was the General.

Following the battle of New Orleans the hero was more adored than ever. During the years immediately following his position in the country became such that though he lost the election of 1824 it was plain that he was the man to watch in 1828. His career continued in the presence of constant and progressive ill health which he made no attempt to hide. He was continually up and down though prostration was allowed to interfere with his activities as little as possible. In 1831 his chronic chest condition exacerbated into inflammation of the lungs and in 1832 he was laid out for four months with "violent cough and costiveness." The "costiveness" suddenly reversed

himself and became an excruciating attack of his old dysentery so that, for a time he had as many as twenty passages in twelve hours. During this illness he complained for the first time of very copious sputum. He called it 'great quantities of flume.' The tortured bronchi had now responded to the perpetual inflammation by the establishment of a characteristic bronchiectasis which assured the patient, though he did not know it, that until the end of his days he would be harassed by flume which would be more and more troublesome as the time went on. So innocent was he of the true meaning of all this sputum that he seemed to think that in coughing it up he was disposing of something valuable of himself. He said that he was sure he would be better if "I can moderately check this loss." In 1825 following the fall beloved of his biographers he had one of his more memorable hemorrhages and tore apart the weakly healed shoulder wounded in both duels. There were already many hemorrhages in his history but he had become so hardened to them that, unless one made him especially uncomfortable, he did not always mention it.

His teeth were decaying with great rapidity, perhaps assisted by the calomel as well as by his general health. During the years 1826 to 1828 most of them disappeared and he was fitted with some false ones which he disliked and would not wear. During these years he was cursed with toothache and jaw ache and increasing headache which by 1828 was beginning to affect his vision. The loss of the teeth cleared up the tooth and jaw aches but did nothing for the headache which became like all the other conditions, a part of him.

In this state he won the election of 1828. What an astonishing physical specimen he was to sit in the presidential chair. Sixty-two years old, racked with pain, fainting from weakness, his constituents brought him to Washington at an unpublicized hour to pare him the overenthusiasm of the crowd. Elections being what they were, he could not be entirely secluded and in his rooms at Cadby's he could be seen and hands shaken by almost anyone. Otherwise he was hidden away and handled like fine china so that he might be well enough to take office on inauguration day. On that day as always he rose to the occasion. Spurning a carriage he walked bareheaded to the White House.

The record of his years as President needs no recapitulation. The two terms stand highlighted by such things as his stands on Nullification, the United States Bank, the National Debt and the Spoils System. Right or wrong they were the

stands of a man of power and strength. His blistering feuds with Clay, Calhoun, and Webster, to name only the most obvious, took more than the average man has to give over a period of years. His occupancy of the White House was accurately known as the Reign of Andrew Jackson and it was accomplished by a tottering scarecrow in deadly agony.

Soon after his inauguration serious changes became evident in his condition. They were not really sudden for it was the old story of the water wearing away the stone, but they were especially to the bewildered clinical innocents of that day dramatic and frightening. The basic septic condition was yielding to even greater sequelae.

Through the spring and summer of 1829 the President a whole system seemed out of sorts. His feet and legs began to swell so that by December they were genuinely dropsical. He complained bitterly of the pain in his chest and his shortness of breath was noticeable to anyone who was in the room with him. His headaches grew excruciating and left him for only a few hours at a time. His vision was very troublesome. He tried a sea bathing holiday and came back to Washington to be felled by fever caused by the miasma arising from a sewer being dug. His stomach was unmanageable. He had fever. In short he had a true nephritis with those nephritic headaches that only a kidney sufferer can understand. There must have been an early cardiac decompensation with a nice rise in blood pressure. His eye grounds had they been seen by a modern practitioner would have caused considerable correspondence between his doctors. Meanwhile of course the pulmonary focus of infection, the malaria, the dysentery, the osteomyelitis and the bronchiectasis were going on and on and on.

The party pleased with his administration wanted him to run again but their misgivings were very plainly put in a note written to Martin Van Buren by William L. Marcy when the question of the vice-presidency was pressing. Said Mr. Marcy: "Of all the candidates for vice president spoken of there is not one who possesses more than barely sufficient qualities for vice-president. General Jackson is advanced in life and to be frank with you is in feeble health. I must say however I wish otherwise that I think the chances are against his lasting five years longer. With the best of those now spoken of for vice president at our head as chief magistrate we should be in a miserable situation."

Such was his own faith in his indestructibility that the President managed when the Party quieted its fears enough to enlist him to carry out

a campaign which included parades on horse back, grueling field trips, speeches, banquets, and all the other performances required of presidential candidates. It was hampered by hemorrhages, bowel flare-ups, bleedings, cuppings, and colic apices, but he won the second term of 1832.

In January of that year somebody at last persuaded him to allow the removal of the pistol ball from his left arm. His final grudging acquiescence was probably due to the fact that the pain in his chest and side was constant and increasing and he was having serious trouble with his shortness of breath. It is a question why he thought that the excision of the ball from his arm should help, though it was still, as always, inflamed and draining. Nobody mentioned the ever present bullet in his chest. The thin yellow old man stood in his bedroom in the White House grasped the back of a chair and a doctor cut out the ball. Then, Mr Jackson rolled down his shirt-sleeve and went out to dinner.

The arm healed, for the first time in twenty years, but the loss of the bullet brought no relief to the pain in his chest and side. Jackson called in Dr. Philip Syng Physick the greatest of them all. Dr. Physick said that cupping would relieve it. Cupping did nothing. Dr. Physick declared that the other bullet, lying so close to the President's heart, was of no consequence. Dr. Physick was strangely apathetic about the general condition of the patient. He said not a word about the dysentery, the swollen legs, the hemorrhages or the assorted other troubles of the invalid. Probably there were so many symptoms that Dr. Physick felt lost in a thick forest of very small trees. Perhaps he felt another sort of helplessness since his patient could not be induced to obey orders. Except for his three specifics, an occasional flier into somebody's patent pain killer and his lancet, Jackson could never be forced to do anything for his health except to lie down when driven by pain or exhaustion.

When his second term of office came to an end and Martin Van Buren was inaugurated, the events of the day must have had an uncanny resemblance to those of the Day of Days of Warren Harding. The wrathlike Jackson, like the shattered Wilson, staggered from his bed to conduct his ruddy, full bodied successor into office before being helped out of the White House into feeble retirement with a doctor on each arm. Jackson left Washington so ill that he was accompanied as far as Wheeling by Dr. John Lawson the Surgeon General, and from Wheeling to Nashville by other competent army surgeons who never left his side until they saw him safely into his own bed

at home. It was a journey of three weeks and it seemed quite possible that he would never make it.

Everything was wrong with him. Amyloidosis is not often seen these days of quick relief of inflammation for it is a condition brought about by chronic suppuration. When established it is implacable. It is the only condition which can account for the grisly last years of the patient and miserable sufferer.

After 1834 he seldom had as much as an hour free from pain. His chest, his side his short breath, all contrived to keep him in agony. His stomach refused almost anything except rice and milk. His right eye, by 1837 failed in earnest. He described it as a "white something approaching the sight" and treated it with weak sugar of lead. In 1838 during a crisis of fever and delirium his head and ear swelled to alarming proportions and his head broke out "all over soars" which he thought a very good thing. His shortness of breath precluded any exercise except a few supervised steps around his estate always ending at Rachel's grave. His days were a procession of all his chronic symptoms with a myriad of painful if passing additional ones.

In this shocking state he had the temerity to travel to New Orleans for a celebration in his honor. En route he hemorrhaged so badly that it was many hours before the bleeding could be controlled and when he arrived he was too ill to make more than a token appearance. Yet, when it was over he managed to get to Jackson, Mississippi where he allowed himself to be the reason for more festivities for two days and nights. Then, after ten days in Vicksburg he, somehow got back to the Hermitage and when he arrived remarked, in a pleased way that his health was about the same as it had been before he left.

This was his last long trip. Once or twice thereafter he tried to ride a little but he had to give it up. 1841 and 1842 dragged by with endless days of pain. He gave up trying to eat with the family and subsided into his invalid chair. He thought his left lung completely destroyed. In 1843 he was acutely ill, if more ill he could be, with bilious colic and cholera morbus as though he were not contending with enough without an attack of gastroenteritis. By this time the amyloidosis had reached nearly every organ in his body.

He gave up his little walk to Rachel's grave. By 1844 he could not walk at all. He lost the power of voluntary motion and was lifted from his sitting position in bed to the same position in his chair. His mind was as clear as ever and with what strength he had he insisted on making constant attacks on his still endless correspondence.

His letters show no diminution of the masterful intellect which seemed to be the only part of him decently alive. By 1845 this beautiful mind rested in a body which was nothing more than a decaying mass. In May 1845 he wrote to Andrew Jackson Donelson that

I am swollen from the toes to the crown of my head and in bandages to my hips. Have had a violent bowell complaint which averaged six to eight passages in twenty-four hours with a constant nausea at my stomach. He told Francis Blair at the same time that he was a perfect mass of jelly from his toes to the upper part of his abdomen. The distended flesh of his dropical legs had probably broken down thus necessitating the bandaging. The dysentery and the nausea a thousand times exaggerated by the progress of the amyloidosis gave him no respite. Then as the ultimate of cruelty the poor old man had hemorrhoids.

At this very late date a painter was sent from France to make a portrait of the old hero. It was very late. The edema had become so pronounced that the artist could use only the brow and the bushy white head and was forced to take the rest of the face from a painting made several years earlier. It was an agony for the patient to sit for his portrait at all.

The end was at hand. On June 1845 his belly had become so distended that Dr. Fesselman of Nashville came hurriedly to tap him. It was a useless effort for the relief was negligible and the patient was exhausted. He sat miserably propped up in bed, unable to lie down. He could not eat.

He could not die. Under opiates for his pain he drifted in and out of consciousness until Sunday June 8th. All that day he was moribund until suddenly at sunset he opened his eyes. His aged son asked whether he could recognize

him to which he answered tartly that of course he could and that he would recognize the others around his bed if someone would kindly fetch his glasses. When they were brought he wiped them neatly on the sheet and perched them on his nose. There was a sentence or two a sigh and a feeble chuckle. He was gone as though all at once. He had decided he had fought too long.

REVIEWS OF NEW BOOKS

THE second edition of Dr Mettler's *Neuroanatomy*¹ is an improvement over the first edition, which was published in 1912. Not only have many of the minor errors been corrected but the author has added a number of new and noteworthy illustrations. One of the principal features of merit is the incorporation in a textbook of neuroanatomy of illustrations and descriptive material for the gross anatomy of the cranium and especially the blood vessels therein. Functional and clinical aspects of the subject have been woven into the fabric of the book and make it especially useful for the advanced reader. On the other hand, the inclusion of much detailed and some controversial material detracts from its usefulness as a textbook for beginning students of medicine.

WILLIAM F. WOODWARD

THE monograph, *Strabismus, a Clinical Handbook* directed primarily to the ophthalmologist deals with the practical clinical methods of examination, diagnosis, and treatment of strabismus. It is not a large book since it contains only 204 pages with 76 plates and drawings.

The book is separated into six chapters divided according to anatomy, physiology of binocular vision, normal muscle balance, concomitant strabismus, paralytic strabismus, and strabismus surgery.

Considerable attention has been given to the significant contributions of Sherrington in the physiology of binocular perception and Chavasse in the development and mechanism of normal and abnormal binocular reflexes, in the hope that more effort will be diverted toward clinical and laboratory study with less emphasis on abstract speculation.

The book contains an outlined method of procedure for working up the patient with concise instructions as to the technique for prism measurement in the six diagnostic, or cardinal, positions of gaze. This is accompanied by a simplified explanation of measurements and their significance. In the chapter on concomitant strabismus the treatment is directed toward correcting the cause and the pathological conditions established by the strabismus. Very little space is devoted to orthoptic training and it is gratifying to note that the author realizes that it is of limited value. The section on surgery gives specific procedures and exact techniques for operating upon the various muscles but the illustrations and the discussion on inferior oblique surgery seems inadequate.

The book is well written and it will be of value to ophthalmologists and all practitioners interested in strabismus.

IRVING FORTENBERRY

NETS AND VISION. By Fred A. Mettler. A.M. M.D. Ph.D. 3rd ed. St. Louis: The C. V. Mosby Co. 944.

STRABISMUS. CLINICAL HANDBOOK. By George J. Epstein, B.A. M.D. Philadelphia and Toronto: The Blakiston Co. 944.

IN her book *Breast Feeding*² the author has given many helpful suggestions and ideas gleaned from years of clinical study avoiding as much as possible detailed technical data. Most of this material, however, is substantiated by scientific investigations.

Breast milk is not offered as the food of all infants. It is suggested that the mother's attitude and problems be thoroughly considered and investigated. The doctors who are willing to take the time and effort to discuss these factors with the mother and particularly the prospective mother will be in a better position to judge which women should nurse. Furthermore, such conferences give the physician an excellent opportunity to present the real reasons for nursing.

The properties of cow's milk and human milk are reviewed and the superior qualities of breast milk as an infant food are listed. It is stated that colostrum apparently does not have any specific value; therefore, the expression of this secretion daily for 3 months prior to the expected birth of the baby may be advisable. This procedure, learned from the experience of dalmatians, has reduced the incidence of mastitis and enhanced the early flow of milk.

Some different points on how to establish breast feeding in the first week of the infant's life are set forth along with sound reasons for the use of both breasts at each feeding. The stipulation to use only a spoon to give a complementary feeding will no doubt meet with some disapproval. The author's suggestion that large infrequent feedings in infancy will dilate the stomach and avoid anorexia in childhood, may also be questioned.

The technique for manual expression of breast milk is given in detail, offering many helpful suggestions about a lost art.

This small volume, devoted entirely to breast feeding, reviews and brings to focus a neglected phase of modern medicine.

L. M. ARTH HARTY

IN the seventh edition of *Recent Advances in Obstetrics and Gynecology*, Bourne and Williams do not presume to review all of the newest and most recent developments in obstetrics and gynecology. Rather as the senior author stated in the preface to the first edition, they attempt to present that new work which has been tested sufficiently to establish it as of real practical and prominent value and to record movements of thought and trends of opinion.

BREAST FEEDING. By F. Charlotte Natch. London, New York, and Toronto: Geoffrey Cumberlege Oxford University Press. 945.

RECENT ADVANCES IN OBSTETRICS AND GYNECOLOGY. By Alice W. Bourne, M.A. M.B. B.Ch. (Camb.) F.R.C.S. (Eng.), F.R.C.O. and Leola H. Williams, M.D. M.S. (Conn.), F.R.C.S. (Eng.), F.R.C.O.G. 7th ed. Philadelphia and Toronto: The Blakiston Co. 944.

The text is divided into sixteen chapters each of which is in essence a monograph on a particular subject. In that portion devoted to obstetrics the chapters on weight changes and water retention in pregnancy, lactation, erythroblastosis and radiology in obstetrics by E. Rohan Williams are particularly worthy of commendation. The discussion of lactation is an excellent summary of material not ordinarily available to the clinician.

Part II devoted to gynecology contains chapters on cancer of the cervix, stress incontinence, sympathectomy, penicillin in gynecology, radiological investigation and diagnosis in gynecology and x-ray therapy in gynecology. Many American readers will be surprised to find that the cytological diagnosis of genital cancer is not mentioned. The Aldridge modification of the Goebel-Stoeckel operation for urinary incontinence is shown in detail. The chapter on sympathectomy deals primarily with the value of sympathetic nerve block in femoral thrombophlebitis.

The text as a whole is an interesting commentary on a number of pertinent obstetrical and gynecological subjects.

JOHN HOFFMAN

THE name Devine is associated with the names of present-day leaders in the field of colonic and rectal surgery. The written word from such a source therefore is not to be taken lightly. It is no doubt a source of embarrassment to the publishers that the name is spelled Divine on the binding. As is stated in the preface, an attempt has been made to reflect the knowledge and wisdom that has been accumulated by the authors on the subject matter and the book accomplishes that purpose.

The book, *The Surgery of the Colon and Rectum*¹ is of convenient size, has good print and is well illustrated with diagrammatic drawings and photographs. In most instances the color illustrations seem to be substantial and not essential. Color however usually has its advantages.

The subject matter deals with the usual and unusual benign and malignant lesions and has been arranged most carefully with a resultant ready reference book for the intern, resident or full fledged surgeon. The amount and variety of detail contained in the book are surprising and would presuppose dull reading but that is not the case. It is very easy reading and is without verbosity. Sentences are short, concise and to the point. Case reports are numerous and well selected to drive home specific lessons.

It would appear that the omission of figures and statistics has been deliberate since there are practically none in the 362 pages. It has been said that statistics can prove anything, sometimes even the truth. Despite the lack of statistics the book is of practical value. From it one will get the authors' reasoning and answers to many questions that one has or should have regarding the problems of colonic and rectal diseases.

THE SURGERY OF THE COLON AND RECTUM. By Sir Hugh Devine, M.D. and John Devine, M.D. Baltimore: The Williams and Wilkins Co. 1945.

All surgeons will not agree, although this reviewer does with the statement "The so-called aseptic anastomosis of the colon has not materially reduced the mortality rate. Neither is there unanimity of opinion regarding the advisability of side-to-side anastomosis, as compared with end-to-side or end-to-end anastomosis."

It is evident that the authors prefer multiple stage procedures in the majority of instances of resectable lesions of the right or left portions of the colon whereas the general trend in this country has been more and more toward one stage operations. The authors' preference is justified on the basis of their statement, "We feel that primary anastomosis of the distal colon, especially segmental resection of the rectosigmoid, should be reserved for the highly or ganglionic clinic."

It is a bit disturbing to one whose training and experience have led him to avoid vaseline intraperitoneally to read of the free use of it on the exploring glove.

The experienced surgeon knows that there are many efficient surgical methods of arriving at the same objective. The purpose of the Devine book is not to cover the entire subject but to present the summation of their experience in the field it covers. The book is excellent from this viewpoint and is well worth becoming fingermarked from use by the student, medical or surgical regardless of age.

CHARLES W. MAYO

WHEN Professor Minder went to lecture at Zurich at the end of 1944 the war prevented his return to Budapest so he utilized this involuntary vacation for a review of his knowledge in the remaining fields of medicine. He discovered that among the many good textbooks there were only a few which could serve as guides for the less experienced. He decided therefore to present urology by explaining first the most important urological problems and in the form of lectures in *Lehrbuch der Urologie*.² In this way he was enabled to describe in great detail topics of practical interest such as tuberculosis of the kidneys, disease of urinary calculi and hypertrophy of the prostate and to discuss problems which apparently lie outside the field of urology but which are important from the viewpoint both of the practitioner and specialist.

Simple methods of examinations and the use of special urological instruments cannot be taught without practical demonstrations. A detailed description of them is of little advantage for the general practitioner. Whatever the author has found as essential in this regard (such as introduction of catheters, the practice of massage of the prostate, or the essentials of lithotripsy, etc.) has been explained by diagrams.

The author did not have his library or clinical resources and very little of the comprehensive statistical data of the urological clinic in Budapest and the urological surgical department of the city of

BERN. *LEHRBUCH DER UROLOGIE*. By Prof. Dr. Med. J. Minder. Bern: Hans Huber, 1946.

Budapest with him in Zurich, so the greatest part of the lectures had to be composed without notes or the utilization of previous publications. He apologizes for omitting the names of authors which had escaped his memory and for not giving references to articles published on the subjects he has written about. All of his conceptions are based on his personal experience gained in large urological departments over a period of 25 years.

The lectures are 25 in number covering 317 pages with 35 diagrams, about 23 pictures of pyelograms, and 20 photographs mostly of specimens. The first lecture is a chronological history of the development of a modern urological clinic—Guyon's clinic for diseases of the urinary tract. The invention of the cystoscope by Nitze in 1888, the development of the urethral catheter and the retrograde pyelogram, better method of sterilizing instruments, improved anesthesia, and the development of kidney function tests all contributed to the reduction of the mortality rates of prostatectomy from 30 or 35 per cent to from 3 to 8 per cent and of nephrectomy from 15 to 25 per cent to from 2 to 4 per cent.

The problem of prostatectomy—suprapubic versus perineal—urinary antiseptics, the development of intravenous pyelography, the resectoscope and transurethral prostatic resection and finally chemotherapy, hormone therapy and penicillin therapy are discussed in the first part of the book.

The remaining 24 lectures cover the problems of urological symptoms: renal function and renal diagnosis from the urological standpoint; renal tumors and nephropathies; Tuberculosis of the kidney; ureter, bladder and genitalia are well covered. The only important therapeutic measure not included is the use of streptomycin.

The lectures on urinary calculi are excellent. Those on diseases and pathological conditions of the bladder are well written as are the lectures on prostatic hypertrophy. The author discusses the theories of hypertrophy, the methods of removal of the gland, treatment of complications, and he includes mention of hormonal therapy.

Infections of the bladder, prostatic seminal vesicles and epididymis of gonorrheal and nongonorrheal origin and the modern therapy of each are well discussed.

Less important or rare diseases have only been touched upon in a brief appendix. These include epispadias, hypospadias, eunuchism, prostatic abscess, orchitis, epididymitis acute or chronic, varicocele and urethral strictures.

The alphabetical index is well and effectively arranged.

KNOWLTON E. BARNER.

GRAY'S *Anatomy of the Human Body* now in its 25th year of publication, has recently (July 1948) been published in its 25th American edition. While fundamental changes have been made in

the plan of this justly famous book, a few changes in text, figures, and editorial policy are noted which may or may not meet with the approval of all anatomists.

The most significant change noted relates to editorial policy. The editorial board of seven professional anatomists has been discontinued in favor of one man editorship. It is not likely that this change in editorial policy will be of immediate importance since the encyclopedic anatomies of this type are changed but little from one edition to the next. In the long run, however, a doubt may be entertained as to one man's competency in the several branches of anatomy to maintain all sections of such a comprehensive work in a state of up-to-date and authoritative revision.

Other changes noted pertain to text, figures, and table of contents.

Only the text of the section on muscles and fascias shows evidence of extensive revision. Muscles are treated individually in regard to action and nerve supply. This is not new but is a reversion to the arrangement followed in most of the standard texts a few editions back. This straightforward treatment of muscle action is much to be preferred over the descriptions by groups as in the 24th edition of Gray and recent editions of other standard texts. Medical students have no difficulty in grasping the concept of synergistic and antagonistic action of muscles, but they do find it unnecessarily time consuming to dig out individual muscle action from the group descriptions in the previous edition and in other texts. The concept of group action is not sacrificed, but is considered appropriately following the study of individual muscle actions. A tedious section on the mechanics of muscle action has been omitted.

Descriptions of regional fascial layers have been amplified and improved. This is an important addition which might well have been carried further.

The table of contents has been condensed from 8 to 4 pages, a great improvement from the standpoint of convenience and utility.

No change is made in the old half functional and half anatomical classification of joints. This reviewer favors the classification of the three major types on a morphological basis: fibrous, cartilage and synovial. This classification puts the emphasis on development and structure, where it logically belongs.

A slight concession to practical anatomy is noted in a reference to J. F. Huber's system of bronchopulmonary segments. The section on surface and topographical anatomy impresses the writer as a completely useless appendage. It is too sketchy to be of practical use and a great deal of its material is taken from other sections of the book. What little new material there is in this section might well be incorporated in other appropriate sections of the book.

The illustrations in the 25th edition are brighter and a few new ones have been introduced, but there

A TOWER OF THE HOW. POET BY Henry Gray, F.R.S. 2nd ed. Edited by Charles Mayo Goss, M.D. Philadelphia: Lea & Febiger, 1948.

is still a serious lack of cross sections and other types of sectional figures

One concept of anatomy exemplified in early editions was that of its usefulness to surgery. Brief comments on regional surgical applications are interspersed throughout the original text. All such practical references have been excluded from recent American editions as a threat to the purity of the science. Many teachers of the basic medical sciences appear to entertain a great fear of contamination by any reference to useful application. Gray was apparently in agreement with the reviewer in his belief that scientific method and thought must be carried through to the so called clinical years and into practice if the highest possible standards of medical education and medical practice are to be achieved. Investigations begun for a practical purpose may lead to profound philosophical deductions, and the reverse may also be true.

The fact that Gray's *Anatomy* has enjoyed great prestige for almost a century without significant change in plan or arrangement of subject matter is a great tribute to the author who incidentally was only thirty-one when the first edition was published. It is no tribute, however, to modern generations of anatomists that no modern text has appeared to compete with Gray or the other bulky texts. In Gray's time the term anatomy covered the field. Now medical students are required to supply themselves with texts of histology, embryology, neuro-anatomy and gross anatomy. Yet the great and bulky old anatomies retain sections on these subdivisions which are now inadequate to meet the needs of medical students, teachers or physicians. Students pay for material they do not use and get an unwieldy book which, in modern regional dissection and study of gross anatomy is extremely inconvenient and wasteful of the student's time.

What medical students need is a textbook of gross anatomy designed to meet present day teaching methods mostly regional in arrangement with more functional implications, better illustrations and a more straightforward readable text.

SYDNEY EVANS JOHNSON

SINCE 1915 when *Treatment by Manipulation in General and Consulting Practice*¹ first appeared it has remained a classic in the field of manipulative surgery. The fifth edition contains much new material with numerous illustrations which enhance its value.

The author's approach to the subject is well balanced and refreshing. There is no attempt made to set forth manipulation as a panacea for all joint disease. Advantages, disadvantages, indications and contraindications are clearly described and details pertaining to each joint are discussed. The conditions which may be benefited by manipulative treatment are confined to four main groups: articular

or periarticular adhesions, subluxations and dislocations of joints, tendons or intra-articular discs adhesions in connection with muscles, tendons or fascia, and certain functional or hysterical conditions of joints and of the spine.

The first five chapters deal with the historical background, the pathology, the prevention and diagnosis of adhesions, and the general principles of manipulative treatment. The remainder of the book is devoted to a detailed discussion of the joints of the upper and lower extremities, the spine, and the sacroiliac joints. This discussion includes a description of the anatomy, prevention of deformity in indications for manipulation and technique. Case histories illustrating the use of manipulative surgery in each joint discussed are included. The concluding chapters are rather sketchy but endeavor to point out the possible dangers of manipulation and the need for adequate after care.

The book is the result of many years of experience and mature evaluation by the author in the field of manipulative surgery. It is a work that should be in the library of all who are concerned with joint diseases.

WILLIAM A. LARMON

THE comprehensive and inclusive report, *Nursing for the Future*² prepared by Dr. Brown is both a challenge and a constructive awakening to the nursing profession as well as allied professions. Science in all of its many phases, industry, economics, business and sociology have kept pace with one another in rapid advancement in order to remain an integral part of modern civilization.

It is the responsibility of the nursing profession to attain and maintain standards of nursing which are comparable and on a level with the educational trends of today. This endeavor cannot be accomplished without co-operation from other professional forces involved nor can it be accomplished through traditional standards and reminiscences. It must be a direct straightforward move with discretionary disregard for time worn measures and custom.

We must maintain adequate nursing care which is both quantitatively sufficient and qualitatively efficient. With this point in mind it becomes necessary to consider nursing from a comprehensive point of view. There must be no differentiation in our basic attitude which will divide professional graduate nurses from licensed practical nurses. Nursing functions must be considered in a like manner.

The role of the graduate registered nurse today and in the future is one of supreme importance and responsibility. It is a task which in order to be successfully accomplished requires the aid of co-operative assistants including practical nurses, attendants and other subsidiary workers. Therefore personal and personnel relationships within all fields of nursing must be in complete rapport in order to allow for co-operative and efficient functioning.

¹NURSING FOR THE FUTURE. A Report Prepared for the National Nursing Council. By Esther Lucile Brown, Ph.D. New York: Russell Sage Foundation, 1948.

²TREATMENT BY MANIPULATION IN GENERAL AND CONSULTING PRACTICE. By A. G. Timbrell Fisher, 5th ed. New York and London: Paul B. Hoeber Inc., 1948.

The burden of this increased responsibility is accordingly greater for the registered professional nurse and she must be theoretically and practically trained to execute her role. She must be trained and educated to the extent that she will possess the knowledge and ability to supervise constructively and instruct other nurses and subsidiary workers to formulate and develop new techniques in nursing care, and contribute to world wide health movements on an equal plane with allied professions.

Professional nursing education today is on a university level, therefore nursing services to maintain progress must be reorganized. The conditions found in many schools of nursing today are incredible. They are not schools in any sense but rather means for student exploitation partially disguised by the organization of the hospitals concerned.

Dr. Brown's report was published under the auspices of the Russell Sage Foundation. The National Nursing Council promoted this study concerned with the reorientation of nursing education.

Concise and precisely this report contains the following recommendations for nursing education at the present time and in the future that

1. The profession take steps to study thoroughly and examine every school of nursing and publish and circulate freely a list of accredited schools of nursing.

2. The necessity for increasing salaries and prestige be thoroughly considered and results expedited.

3. Nonprofessional nurse programs of training be established and maintained on a national basis with definite prerequisites for licensure.

4. The nursing profession establish and maintain definite levels of professional achievement in order that promotions and advancement will be governed by preparation, experience and achievement.

5. The nursing profession allow for education of the public to the problem at hand and thereby obtain co-operation, support and participation.

The health and hygiene needs of society today prompted this study and Dr. Brown has extensively and intensively presented these needs as well as recommendations for meeting them in a modern progressive manner. These recommendations are only the beginning for the reorientation of the profession and it is the responsibility of each and every member of nursing to participate whole heartedly in this great movement.

COLLECTIVE REVIEW

SEPARATION OF THE CAPITAL FEMORAL EPIPHYSIS IN THE ADOLESCENT

SIDNEY L. STOVALL, M.D., San Antonio Texas

SEPARATION or slipping of the capital femoral epiphysis in the adolescent is one of the most controversial subjects in the orthopedic literature. Although the term "slipped epiphysis" is a misnomer it has enjoyed common usage and will be employed in this paper despite the fact that various names such as epiphyseolysis, sliding of the femoral epiphysis, adolescent coxa vara, osteochondritis of the neck of the femur, epiphyseal fracture of the hip joint, epiphyseal coxa vara, and epiphyseal coxa anteverta have, at various times, been introduced.

This condition consists of a separation of the head and neck of the femur occurring at the metaphyseal side of the capital femoral epiphysis, with a subsequent gradual or sudden change in the relation of the head to the neck. The head, contrary to its title does not slip but remains in approximately its normal position in the acetabulum, while the neck rides upward and forward, resulting in external rotation and slight shortening of the extremity.

Slipping of the femoral epiphysis at its proximal end was first recognized by Brousseau in 1867. Not until 1888 however was the condition described by Muller. Subsequently numerous articles have appeared in the literature devoted to the various phases of etiology and treatment. Key, and Noble and Hauser in 1926 in extensive reviews of the literature, did much to stimulate interest in this condition, and since that time extensive study has been carried out.

The purpose of this paper is to review the extensive amount of work which has been done on this subject so that a clearer understanding of the problem at hand may be gained.

INCIDENCE

Slipped epiphysis in the adolescent is the most common cause of disability involving the hip. Scott placed it fourth as the cause of all disabilities involving the hip including tuberculosis. Waldenstrom, reporting from Sweden, found that of 16 000 patients seen in the Orthopedic Hospital over a 5 year period 111 or 1.70 per cent, had slipped epiphyses as compared to 1.84 per cent with Legg Perthes disease. Sullivan stated that at the Boston City Hospital Clinic an average number of 12 patients a year was seen. Key described slipped epiphysis as the most common cause of hip disability in the adolescent, pointing out that less than 10 per cent of the cases of tuberculosis of the hip begun at this time. Legg Perthes disease is well recognized as occurring in a younger age group. Wilson (54) in reviewing the fractures of the neck of the femur in children seen at the Los Angeles General Hospital, reported that within a period of 10 years only 10 fractures of the femoral neck were seen.

This condition then is characteristically one of adolescence. This is even reflected in the different ages of onset in the two sexes, the earlier onset in females corresponding to an earlier peak of adolescence. Males are more commonly affected than females. Although MacAusland reported an incidence of 80 per cent males, and Ferguson and

From the Department of Bone and Joint Surgery School of Medicine Northwestern University Chicago, Illinois.

4. Circulatory changes in the femoral head. Contrary to the popular belief that the nourishment of the femoral head in infants and children is due to a patent artery in the ligamentum teres which penetrates the head, Wolcott in studying the femoral head found that in infants and children the artery of the ligamentum teres does not penetrate the femoral head or contribute to its nourishment until about the twelfth or fourteenth year of life, and in 20 per cent of the cases never penetrates the head. He pointed out that this fact may have some bearing on the etiology and Carrell and Carrell attributed the large percentage of aseptic necrosis of the femoral head in fractures of the neck in children to this fact.

5 Psychologic changes. This period often engenders a much greater desire to excel in sports and other physical activities and a growing resistance to restraints imposing normal rest.

Theories of etiology Three principal theories have arisen to explain the occurrence of the lesion drawn from the above collection of facts and from observation of patients clinically and pathologically. It is probable that more than one theory may be active in any given case with various factors interacting to produce the lesion.

1 Traumatic theory Trauma apparently plays a very definite part in the production of slipped epiphysis, and many authorities adhere to this as being the sole cause of the condition. Most authors agreed that trauma of either slight or great degree was the most common precipitating factor in the onset of symptoms, although there was disagreement as to whether trauma alone could displace a normal femoral epiphysis. Kleinberg and Buchman (28) Ghormley and Fairchild and others pointed to the physiological changes in the epiphysis which render it mechanically more susceptible to traumatic separation, pointing particularly to the more oblique position of the epiphysis, the widening of the epiphyseal plate and the change in the angle of the femoral neck. They felt that these factors in the presence of trauma were the principal predisposing factors in the development of the lesion. Key stressed the thinning of the periosteum, which in childhood is thick and strong. In adulthood after the bone becomes completely ossified the periosteum then becomes thin. Key felt that with this rapid thinning over a still cartilaginous union, sufficient weakening was produced in this link between the head and the neck to allow separation induced by even minor trauma. Wilson (55) also stated that the periosteum was the chief sustaining band between the epiphysis and the diaphysis, and quoted experiments carried out by Oliver and

Poland on cadavers in which this was demonstrated. Ghormley and Fairchild, on the other hand demonstrated a case of nearly complete separation of the epiphysis in which the periosteum was still intact and believed that the thinning was secondary to stretching rather than a primary contributing factor to the separation.

Badgley Sever, and Ghormley and Fairchild agreed with Walsley's theory that the mechanism of displacement is produced by an extension force applied to the head of the femur locked in the acetabulum. Walsley showed that at 15 degrees extension the head of the femur is locked securely in the acetabulum further extension being precluded by the iliofemoral or "Y" ligament of the femur. Hyperextension beyond this point, he believed would result in motion at the epiphyseal line.

Taylor believed that in the acute type with a single injury and sudden onset of symptoms, a fracture is sustained through the juxtaepiphyseal line with resultant loss of continuity. Sutra, and others, believed that the pathological findings are those of fracture through the epiphyseal line with subsequent attempts at healing. Brogren believed that trauma plays a very important part in the production of slipped epiphysis and suggested the term epiphyseal fracture for the acute traumatic type.

If trauma is accepted as the only cause of slipped epiphysis, even with the added factors of physiologically increased vulnerability of the epiphysis, it becomes difficult to explain the relative infrequency of this condition in adolescents who are repeatedly exposed to trauma of all degrees of severity. Likewise the fact of fairly frequent bilateral occurrence, the second hip often being affected while the first is under treatment, is hard to understand on the basis of trauma alone. Foley stated trauma can never displace the normal upper femoral epiphysis if it is severe enough it will fracture the neck, leaving the epiphysis undisturbed. He quoted the experiments carried out by Allenshaw and Wood Jones to demonstrate this. Howorth in 1941 considered trauma only an incidental cause of slipping.

It appears that there must be in these adolescent girls and boys some additional factor which makes them more susceptible to the usual trauma than the majority who do not develop slipped epiphysis. If a softening or loosening of the epiphysis occurs, it is easier to understand how even minor trauma, such as the static effect of overweight, muscle pull, and slight injuries can produce displacement. Many authors have proposed an endocrine background for such changes

Howorth an incidence of 56 per cent males, the average ratio in all of the reported cases was approximately 2 to 1 in favor of the males. All authors agreed that the lesion appeared somewhat later in males than in females. The mean age of onset in the girl was at 12 years, and in the boy at 14 to 15 years. Ferguson and Howorth, in a series of 70 cases, reported also a seasonal variation corresponding to periods of greater activity thereby adding one month to the summer for the boys, to include the football season.

Although there was considerable variation in the reports of different series, in the ratio of involvement of the left to the right hip, the average ratio for the reported cases was approximately 5 to 4.

There was even greater variation in the reports on the number of cases with bilateral involvement, possibly related to interest and study of both hips in patients with apparently unilateral involvement. The average incidence reported was the same as in those cases reported by Key before 1926 or approximately 15 per cent.

ETIOLOGY

In considering the etiology of this disease, the outstanding fact noted was that almost without exception the onset occurred during adolescence. Likewise, in the individual child, it was reported by several authors, the parents described the onset as following a period of "growing like a weed" although there had been no actual measurements, periodically of the height of these children preceding the onset.

It is of interest to review some of the changes occurring in the body during the adolescent period with a view toward their possible bearing upon this condition.

Local changes at the capital femoral epiphysis. Key, Badgley, Kleinberg and Buchman (28) and others have pointed out a number of changes which normally occur at this epiphysis and the surrounding area during this period.

1 The epiphyseal plate which normally occupies a horizontal position during childhood, assumes a more oblique relationship during adolescence.

2 There is a spurt of increased growth at the epiphysis with some physiological widening of the epiphyseal plate.

3. Thinning of the periosteum and the retinaculum of Weitbrecht connecting the head to the neck osseous.

4. The neck of the femur lengthens and increases in density lessening its angle of junction with the shaft.

General changes in the body

1 Changes in height weight relationship. Noble and Hauser have shown that the weight curve reaches its greatest relative peak during this period. Also at this time the so-called Froehlich's syndrome is likely to develop. This condition has recently been termed by Warkany as benign adiposogenital dystrophy of adolescence, and is only slightly less common in girls than in boys. As slipped epiphysis is common in this group it may be described more fully. These children show not only adiposity particularly in the mammary and abdominal regions and in the upper arms and thighs, but also exhibit increased skeletal and muscular development, and are often described as "overgrown." Relatively small and sometimes proportionately "underdeveloped" genitalia are often present in the males. Corrected basal metabolic rates in these children are normal or elevated and the obesity usually subsides after maturity is reached. The genitalia then appear normal. Warkany, Newburgh, Bruch (9, 10) and others have emphasized the absence of hypothyroidism in these children, and believed that the condition might be due to transient changes in the endocrine balance with possible hyperfunction of the thyroid or anterior pituitary.

Other children at adolescence show a sudden, rapid increase in height, becoming much taller within a short period of time.

2 Chemical balance. Johnston (25, 26) has shown that the adolescent child exhibits a marked tendency toward the development of negative nitrogen and calcium balances. This is particularly true in the "overgrown" child described above. He studied 3 patients with slipped epiphysis, all of whom were found to have negative, or very low calcium balances, but which could be corrected or improved by the administration of vitamin D. He recommended prophylactic administration of calcium with vitamin D in the preadolescent period. Ghormley and Fairchild reported blood chemistry studies on 4 patients in whom the calcium was normal or high. Very few reports were made on blood chemistries in these patients although it was agreed that neither chemically nor pathologically was there found evidence of rachitic changes.

3 Endocrine changes. The exact nature of the endocrine changes of adolescence has not been worked out. It has been shown by Johnston (25, 26) that hyperthyroidism in children reaches its peak at this period, often subsiding as maturity is reached. Even more often hypothyroidism is present in a mild degree, evidenced not by obesity but by delayed growth and development, fatigue and inattention.

tendency to pannus formation. The synovial fluid was often increased in amount, and frequently softening of the epiphyseal line could be felt with an instrument. Microscopic examination reveals edema and hypervascularity of the synovia with a collection of round cells about the small blood vessels. Cultures were persistently negative attributed to technical difficulties or to failure to obtain the culture early enough. He concluded that the primary condition was a synovitis of the hip during a period of rapid growth and that this lesion caused circulatory changes in the epiphyseal disc resulting in decalcification and softening. Foley confirmed the findings of Howorth, but brought up the question of whether the synovitis is a result of or a cause of the slipping. Balensweig also a believer in an infectious etiology believed that there is a metastatic infection in this condition as well as in Legg Perthes disease and osteoarthritis similar to that in hematogenous osteomyelitis, with localization here in the juxtaepiphyseal region. He preferred to call this osteochondritis of the hip and believed that in the first decade of life one may have Legg Perthes disease in the second decade slipped epiphysis, and in the third decade osteoarthritis. Capener reported 2 cases of acute infection with fever at onset, in which intra-articular hemorrhage was later thought to be responsible for the slight temperature elevation, but when first seen infectious metaphysitis was considered.

The opponents of this theory pointed out consistent failure to obtain positive cultures, the general well-being of the patients, absence of fever or other systemic manifestations and normal sedimentation rates.

MECHANICS OF SLIPPED EPIPHYSIS

In order to understand slipping of the epiphysis, it is necessary to review the anatomy and mechanics of the normal hip joint (22-34). This is a typical ball and socket joint, the head of the femur fitting closely into the acetabulum for an area extending over nearly half a sphere. At the margin the bony cup is still more closely embraced by the glenoid labrum so that the head is held in place by that ligament even when the fibers of the capsule have been divided. The capsule, which completely invests the head and a large part of the neck, is strengthened anteriorly by the iliofemoral ligament which curves around the anterior surface of the neck of the femur and the joint, and prevents extension of the lower extremity beyond a straight line with the body. Blood supply reaches the head via vessels running along the neck in reflected portions of the

capsule. The major blood supply arises from the medial circumflex artery and lies within the posterolateral quadrant of the visceral capsule.

This joint can move around three axes: a transverse axis around which extension and flexion occur, a vertical axis for medial and lateral rotation, and a dorsoventral axis for adduction and abduction. The three axes intersect in the center of the head of the femur. The transverse axis lies somewhat anterior to the center of gravity of the body and in the erect position, there is a tendency for the pelvis to rotate backward being checked normally by the tension of the iliofemoral or "Y" ligament. The vertical or mechanical axis falls medial to the shaft of the femur as the shaft inclines downward and medially. The dorsoventral axis passes between the margins of the acetabulum and through the center of the femoral head.

The relation of the neck to the shaft is also important in motion at this joint. If it turned directly medially from the shaft, motion at the joint would be angular, and marked change in relation to the articular surfaces of the head and acetabulum would result, for example, in transit from flexion to extension. Actually the neck turns obliquely upward to an approximate angle of 120 degrees, and also has normally about 12 degrees of anteversion so that motion at the joint is always rotatory and gliding as well as angular and therefore the articular surfaces always remain in close contact.

The direction of thrust of normal body weight when the body is in the erect position is downward backward and outward. The head of the femur is set like a cap on the upper convex end of the neck with the epiphysis looking obliquely upward and medially. When separation occurs it always is on the diaphyseal side of the epiphysis.

Assume an individual standing erect. He is an overweight adolescent boy who has developed a change in his epiphysis which renders it softer and more fragile than normal. As he stands, with the pressure of his weight pushing downward and backward on the head, the head is supported posteriorly by the acetabular margin and locked securely in place anteriorly by the iliofemoral ligament, which blocks any further forward progress of the head. The force is transmitted therefore, through the epiphysis to the neck. The attachment of the epiphysis posteriorly and inferiorly is supported by a projecting lip or buttress of bone and by the periosteum which is thicker and stronger here than elsewhere. Anteriorly however the periosteum is the only connecting support and is rather thin. Consequently as Milch has emphasized the cartilage of the epiphyseal

2. Endocrine theory There are a number of factors which support the theory that unusual softening of the epiphysis leading to separation may have an endocrine basis. First is the fact that the slipping always occurs at the peak of rapid growth at a time when profound changes are occurring in the body under the control of incompletely understood endocrine influences. Ferguson and Howorth, in a report of 70 cases, stated that in the few cases which occurred before the actual spurt of adolescence other factors such as overweight and trauma were unusually prominent.

The fact that the lesion is often bilateral also leads one to suspect that a similar change is occurring simultaneously in both epiphyses.

There is some suggestion of increased familial incidence, although there are few detailed reports concerning this point. Scott reported one case in which the father also had a coxa vara, and Compere reported the case of a family in which two brothers and a sister were affected with slipped epiphysis as they approached adolescence. The fact that has been repeatedly noted by many authors was that the lesion is very often associated with a particular type of body build primarily the so-called Froehlich type individual and secondly the very tall thin person. The exact nature of endocrine disturbances in these individuals has not been determined. Yet, it has been well shown that particularly in the obese children, there is a much higher familial incidence of obesity and also of diabetes mellitus than in the normal population.

Noble and Hauser stressed the importance of endocrine factors. MacAusland reported 42 per cent of 45 patients to be obese or with other unspecified endocrine disturbance. Forrester Brown reported the finding of such changes in 86 per cent of 11 cases. Brogden, in 65 per cent of 57 cases, Badgley in 5 per cent of 27 cases. Ghormley and Fairchild, in 26 per cent of 55 cases, and Pomeranz and Sloane (40) in 40 per cent of 101 cases. Scott stated that "Endochondral ossification is largely dependent upon function of the sex glands and the hypophysis, for many cases point to disordered function of these glands," but gave no evidence of their disordered function. Ghormley and Fairchild stressed the fact that 61 per cent of their 55 patients showed normal or only slightly excess weight. They did not state whether measurement of weight was judged in relation to height, which in overgrown children is often also above the average.

Wilson (57) also brought out the fact that even when slipping occurs on one side early in adoles-

cence and is quite severe, the final shortening as compared to the other side is usually relatively slight. He believed that in these cases early closure occurs on the involved side as well as on the uninvolved side indicating a metabolic disturbance.

The fact that these lesions may occur gradually with absolutely no history of trauma greater than the normal trauma of weight-bearing and muscle pull across the joint also suggests that there must be abnormal softening or loosening before slipping can occur.

As to the actual mechanism in which ossification is disturbed, little is known. Benjamin and Miller found that children suffering from thyroid deficiency encounter a disturbance of ossification involving the proximal femoral epiphysis. In cretins the normal epiphyseal plate is replaced by a disc type zone of solidly calcified cartilage in apposition to a transverse layer of bone. This type of union is incapable of resisting normal stress and is often displaced. Waldenström believed that there is a disturbance of ossification at the junction of the epiphyseal cartilage with the metaphysis during puberty. Because of this, the disturbed cells do not hold firmly enough to resist the pressure exerted when weight is borne so that a displacement occurs in the zone of ossification. He stated that the cause of this disturbance is obscure but there may be sufficient endocrine change to effect this appearance without external manifestation. Bernstein and Arens corroborated this theory and felt that slipped epiphysis is analogous to vertebral epiphysitis and Osgood Schlatter's disease. Snodgrass reported the case of a 15 year old colored boy with slipping of the epiphysis and Osgood Schlatter's disease of concurrent onset.

3. Infectious theory The support of the infectious theory is rather weak and has few adherents. Ferguson and Howorth, in 1931 stated that they believed that "weakening of the epiphyseal disc is due to vascular stasis about it secondary to sclerotic changes in the soft tissues about the femoral neck. The most probable cause of the sclerotic changes in the soft tissues is a previous, or occasionally concurrent, infection a subacute arthritis, or rarely infection of the neck. Seventy-five per cent of the patients in their series of 70 cases showed mild infections in other parts of the body. Howorth later studied 17 hips in the pre-slipping stage and 23 hips in the slipping stage, and reported that early the capsule of the hip was edematous and thickened the periosteum of the neck and synovial membrane were almost always thick, red, softened, and vascular with a

The line of demarcation between bone and cartilage is fairly well preserved, the columnar arrangement of the cartilage persisting although it is somewhat irregular and the number of cells is reduced. The resting cartilage appears fairly normal but there are scattered splits and in some areas, fibrous tissue apparently filling similar splits in an effort at repair. Some of these areas of fibrous tissue are undergoing ossification. The osteoid tissue at the junction with the metaphysis is irregularly disposed as is the newly formed lamellar bone. As the disease progresses the same changes become much more marked until, in advanced stages, the normal characteristics of the cartilage-bone contact zone are completely lost. At that time enchondral ossification has been completely replaced by irregular fibrous bone formation. Areas of degeneration, hemorrhage, and necrosis appear. The authors described the picture as one of a completely chaotic arrangement of normally functioning cells interspersed here and there with areas of necrosis and areas of hyper-vascularity.

ROENTGENOGRAPHIC FINDINGS

The roentgenological appearance of the lesion may be predicted from the previous discussion of pathology.

Early or preslipping stage. Here there is seen only widening and possibly slight irregularity of the epiphyseal line with a little later slight rarefaction of the adjacent bone of the metaphysis. Careful comparison should be made to the opposite hip and a lateral roentgenogram of the suspected hip should always be made because often an anteroposterior view is confusing and may not reveal the true extent of the pathology.

Slipping stage. Mayer and Pomeranz (39) reported that the earliest roentgen evidence of slipping of the epiphysis was the disappearance of the slight bulge or hump on the upper margin of the head and neck junction, and conversely the appearance of a slight prominence of the lower margin. Milch stated that very early by lateral stereoscopic views a slight slipping in the anteroposterior plane could be demonstrated before any upward displacement occurred. He pointed to the subcapital shadow which as he demonstrated experimentally in monkeys by loosening their epiphyses and taking roentgenographs of the femurs (in different positions) with known amounts of artificial slipping is actually the anteverted proximal end of the neck seen first in profile and then end on. The diminution in width of the epiphysis as seen in an anteroposterior view after slipping has occurred is due to the backward rotation of the

epiphysis, the posterior and inferior margin of which is often visualized as a dim shadow through the shadow of the neck. Milch, Wilson (57), Kleinberg and Buchman (28) and others have pointed out that the roentgenographic appearance may vary with changes in position of the extremity and may lead to false belief that reduction of a separation has been obtained when the film is made with the leg in internal rotation due to superimposition of the shadows of the epiphysis and the anteverted end of the neck.

In traumatic separation of the epiphysis the line may appear hazy because of the presence of hemorrhage.

Late changes. The neck appears shortened and greatly thickened and the outline of the head is very irregular and flattened and often irregularities due to arthritic changes appear.

CLINICAL MANIFESTATIONS

Key gave a classic description of the clinical manifestations and little can be or has been added to this.

The onset of symptoms in this condition may be gradual and insidious or may appear very suddenly or there may be a sudden exacerbation of previously mild symptoms, occasioned by sudden acute slipping.

The first symptom is often mild pain in the hip or more commonly on the medial side of the knee. A slight limp may appear intermittently gradually becoming persistent. The patient may notice unusual fatigue on walking or standing. The pain at first is completely relieved by rest, later becoming more persistent. There may be no history of trauma, or if there is it is often found that mild symptoms have been present for some time preceding it. Such patients infrequently consult a physician until symptoms have been present for several weeks or even months, simply considering them as growing pains. Careful examination at this point will usually disclose slight limitation of internal rotation the patient tending to hold the leg in slight external rotation and possibly some limitation of abduction. At this early period there may be no other signs than those mentioned and these are elicited only by very careful comparison with the opposite hip. Widening of the epiphysis is shown in the roentgenogram with no or slight separation of the epiphysis. Diagnosis made at this time offers the best opportunity for successful treatment therefore it is important to stress the fact that any limp in an adolescent, particularly of the body types most commonly affected, should be carefully investigated without delay. Once this process has begun

plate begins to appear wider anteriorly and superiorly narrowing slightly posteriorly as the neck of the femur assumes a gradually increasing degree of anteversion. Milch felt that, in addition as the leg is put into eversion during activity, the head follows it as it rotates until the ligamentum teres becomes taut. As the head can no longer follow if the epiphysis is softer than normal, an acute slipping in the anteroposterior plane occurs at this point, the neck assuming a more anteverted position than the head therefore rolling out into external rotation. It is only after the neck becomes so anteverted as to be no longer supported by the epiphysis that it begins to slip upward. At this early stage, before upward slipping occurs, X-ray studies disclose the characteristic early widening of the epiphysis. Milch stated that this is only apparent and is actually due to the shadow of the anteverted proximal end of the neck. Kleinberg and Buchman (28) in surgical observation of early cases, have observed the characteristic wedge-shaped deformity of the epiphyseal plate and noted that union with the head and neck still seemed quite firm. Probably both observations are correct as anteversion and slipping occur gradually, with concomitant repair process, so that the epiphysis actually does become widened anteriorly and superiorly at the point of greatest strain.

As the process progresses, the neck becomes more anteverted and the shearing force of body weight plus muscle pull, particularly in hyperextension, or with sudden external rotation force, causes the neck to gradually slip upward and forward on the head with a consequent rise in position of the greater trochanter and loosening of the iliofemoral ligament, allowing for further external rotation and limitation of abduction by approximation of the trochanter to the side of the pelvis. External rotation is maintained by the external rotators, which are stronger than the internal rotators, and by the altered action of the iliopectineus, which tends to rotate the distal fragment outward when there is separation of the head and neck. As the neck gradually rises, the head may rotate into a position of flexion while the femur if the head is in its normal position has a position of hyperextension. The posteroinferior border of the neck in extension may sink into the cancellous part of the head so that the head overlaps the lower and inferior aspect of the neck and produces apparent shortening of the lower margin. On the other hand, the protruding end of the neck superiorly gives the appearance of lengthening and may become rounded off to articulate with the acetabulum. As the metaphysis first rises

above the epiphysis, the overlying cartilage becomes thin and bluish, the periosteum is markedly stretched and may become torn and fracture may occur at the anterosuperior margin of the junction of the epiphysis and metaphysis through the epiphyseal line. Inferiorly the periosteum is rarely disrupted but is torn up from the lower surface of the neck. If rotation of the head occurs, it may be twisted so that its fibers run obliquely upward toward the epiphysis.

All of these changes may occur suddenly in the presence of appropriate trauma, and the epiphysis may suddenly be completely separated from the shaft.

PATHOLOGY

The gross appearance of hip joints involved in this process is easy to understand in view of the above facts. Early there has occurred slight anteversion of the femoral neck, as compared with the normal, opposite side, with a wedging of the epiphyseal plate with its base anteriorly and superiorly. The articular cartilage appears normal, and there is no bone atrophy. The lower margin of the neck is normal in length while the upper margin may be slightly longer due to widening of the epiphyseal plate. In early slipping the cartilage superiorly is thinned along with the periosteum, and bluish, as the cancellous bone ablates through. There begins to be a little lengthening of the upper margin. Cartilage of the lower margin appears normal and may begin to overlap the lower posterior margin of the neck so that this appears shortened. Late in the disease the crescent shaped head with its epiphysis, may have been far forsaken by the upper and anterior surfaces of the end of the metaphysis which have been covered with fibrous tissue and smoothed off to form part of the articulation with the acetabulum which has become egg-shaped to fit. The lower part of the head completely overlaps the lower inferior part of the neck, and fuses with it. The bone of this part of the neck is markedly thickened to withstand the extra strain imposed upon it in the inefficient joint.

The microscopic pathology has not been studied adequately in the very early cases due to the fact that specimens were difficult to obtain at this period. Howarth's studies of 40 hips at a fairly early stage in the process have been mentioned. He attributed the findings to infection. Sutra examined specimens removed at operation and reported "no evidence of rickets, osteomalacia or specific osteitis fibrosa." Kleinberg and Buchman (28) in a study of epiphyses removed early at operation, gave a good description of early changes.

vitamin or mineral imbalances, and other measures directed toward improvement of general health are of value in speeding ossification of the epiphysis.

Because further slipping has frequently been noted to occur while the patient was under conservative treatment (16 55), and in an attempt to accelerate healing, various surgical procedures have been devised.

Jahss (24) attempted to obtain a premature fusion of the epiphyseal line by hammering of the greater trochanter with a Cotton mallet while there was still fairly good position. Others drilled through the epiphyseal plate from the upper surface of the neck, hoping to obtain better vascularization and earlier fusion. Ferguson and Howorth drilled and added silver bone grafts or bone pegs through the holes in an attempt at immobilization of the epiphyseal plate. Wilson (57) inserted a Smith Petersen nail through the trochanter and neck into the head in an effort at fixation to prevent further slipping. He reported 14 cases in which the Smith Petersen nail was used with excellent results in 10 cases, after a 4 to 34 month follow up period. Compere advocated the use of threaded wires instead of the Smith Petersen nail to secure fixation. Kleinberg and Buchman (28) completely removed the epiphyseal plate.

Stage of gradual slipping. At this point slipping has advanced more than three-eighths of an inch, but there is still union between the head and neck, as the epiphysis is only partially displaced and there is usually a variable amount of callus formation between the lower margin of the neck and the overlying lower margin of the displaced head, further strengthening the attachment maintained by concomitant fibrous and bony repair in the weakened epiphyseal junction.

Great discussion has arisen as to the necessity or advisability of accurate replacement of the epiphysis. It was generally believed that if not corrected, arthritis is prone to occur as a late sequel. However a high incidence of similar complications has been reported in patients treated by manipulation, and, especially by open reductions. Moore felt that any treatment further endangering blood supply to the epiphysis encourages development of changes in the overlying articular cartilage. Ferguson and Howorth stated that average function is less with greater displacement, but this is partly accounted for by greater traumatism in treating them.

Apparently much of the deformity and limitation of function at this stage is due to muscle spasm, as it has long been known that rest alone

will result in improvement of function. Ferguson and Howorth, and Wilson (57) have treated patients with mild displacement conservatively with good results. The only large series reported was that of Moore, who treated mild to moderate displacement by immobilization in casts with no significant residual functional impairment in over 47 per cent of his cases.

Manipulation has been a widely used method of treatment. The most commonly used was the method described by Whitman. It is performed under full anesthesia and consists of forcible flexion and internal rotation followed by abduction of the thigh with simultaneous strong downward traction on the leg. In considering manipulation it must be remembered that leverage is great in this situation because of the long lever arm of the femoral shaft, and as a result pressure is exerted upon the small head. Manipulation must be very careful and gentle if trauma to the articular surface of the head is to be avoided as well as further trauma at the epiphyseal junction and damage to its blood supply. It is obvious that if slipping has progressed for a considerable period of time and repair processes have occurred rendering the malunion again fairly firm, manipulation will have small chance of success. The period in which good results may be obtained was placed variously at 2 months from onset by Ferguson and Howorth, not over 4 months by Brogden, while Bentzon felt that it would be successful up to 6 months from the onset of symptoms. The amount of displacement and callus formation as determined by roentgenography, is also a helpful guide. Pomeroy and Sloane (40) have pointed out that x ray films made following manipulation, with the leg in internal rotation, had given many surgeons a false opinion that reduction had been obtained, whereas actually there was only superimposition of the shadows of head and neck, and the deformity persisted. Waldenstrom was of the opinion that closed reduction under anesthesia should never be done because only a few of the so-called successful reductions showed improvement and in one-fifth of his patients so treated aseptic necrosis resulted. Many failures with this treatment have been reported, often with progressive loss of motion, and with pain in the hip following the procedure (1 14, 16 27 40 42, 43 44, 48). Good results have been obtained in early cases best in those with acute, early separations.

Perkins, Wardle, and others advocated traction and have obtained fair results. The question arises as to whether the results with surgical procedures are adequate to justify the attempt at correction of the deformity. Many believed that

there is constant danger of sudden, acute slipping due to a fracture through the weakened epiphyseal line. When this occurs the patient usually has sudden, severe pain in the hip, often accompanied by marked muscle spasm, external rotation of the leg, and marked limitation of all motions.

In those cases in which the gradual process continues, the patient's limp becomes persistent, often with increase of pain, although not necessarily so. The patient notices increasing weakness and fatigability in the affected extremity. Objectively the patient is seen to walk with a decided limp, with the pelvis tilted downward on the affected side and the gluteal fold lower on that side. A mild compensatory scoliosis develops with the lumbar curve toward the affected side. The trochanter is elevated on the affected side, usually lying above Nelaton's line. There is mild to moderate atrophy of the buttock and thigh. No tenderness can be elicited. The leg lies in external rotation and the patient, as he walks, holds it in this position. Internal rotation is sharply limited and there is usually a marked limitation of abduction due to impingement of the trochanter on the pelvic wall. A mild flexion deformity is often present. Active and passive motions are about equal. These patients generally show no other sign of illness of any kind, have no fever, have normal sedimentation rates, and appear quite healthy.

The danger of progressive displacement remains until the epiphyseal cartilage is completely ossified and is, therefore, present over a period of from 1 to 3 years from the time of onset. After ossification has occurred, there will be no further displacement. Due to irregularities of the displaced head and proximal end of the neck, and the poor fit in the acetabulum and possibly to damaged blood supply occurring in the process, with necrosis of overlying articular cartilages, these patients often develop residual arthritic changes at a variable period after reaching the final stage with healing of the epiphysis. Ghormley and Fairchild pointed out that the many cases of morbus coxae senilis probably represent residuals of old slipped epiphysis.

It has been pointed out by Key and others that the severity of symptoms does not always correspond to the anatomical deformity present, and that each case must be carefully considered individually.

TREATMENT

The variety of procedures employed in the treatment of this condition is evidence of the fact

that none is completely satisfactory. It was quite generally agreed, however, that the earlier treatment is begun the greater is the opportunity for success. The importance of early recognition and diagnosis and early institution of therapy was repeatedly emphasized.

In choosing the type of treatment to be instituted, an attempt must be made to determine as well as possible the pathological changes that have occurred. The duration of symptoms, the time since an acute displacement, the age of the patient, x-ray evidence as to the amount of displacement and extent of callus formation, and functional ability of the joint must be considered. For purposes of discussion the disease may be divided into several more or less arbitrary periods.

Pre-slipping or slight displacement. At this stage there may be present only a widening of the epiphyseal line or if slipping has occurred, it is less than three-eighths of an inch or one centimeter. Patients seen during this period show the best results. It has been pointed out by Howorth, Milch, and many others that once changes begin, the epiphysis is likely to undergo premature ossification due to the damage it has sustained. The period required varied considerably in the reports of several authors, but may be as short as 8 to 12 months or slightly less. In some cases, however, it may extend for 2 to 3 years. The patients must be followed, regardless of the type of treatment used, until there is good x-ray evidence of ossification through the epiphysis and firm union between the head and neck. During this entire period they must be carefully protected from any strain likely to produce further slipping at the softened epiphysis.

Conservative treatment may consist of simple rest in bed with freedom from weight-bearing. However, acute slipping occasionally occurs at bed rest. Some authors have advocated rest, with walking permitted on a raised shoe on the sound leg, and crutches, or a caliper brace to avoid weight bearing. Such a brace with the addition of constant maintenance of internal rotation has been used with better results (32). The danger of added strain on the opposite hip with possible development of a bilateral lesion must be constantly kept in mind. Plaster of paris casts have been used for periods of 2 to 9 months, to maintain a position of abduction and internal rotation. In some cases efforts to avoid the excessive atrophy and tendency to stiffness of the hip have been made by bivalving the casts and using careful physiotherapy.

General measures such as weight reduction, elimination of foci of infection, the correction of

they are not, reporting that better function was retained in untreated hips, even with deformity, than in those subjected to surgery even when good anatomical reposition was obtained. Howorth, in discussing the paper of Ghormley and Fairchild, stated when the epiphysis has already slipped the chances of securing a good result are not good regardless of the method of treatment. Any type of reduction is poor treatment because the head must be entirely separated from the neck in order to obtain reduction. And when the head is completely separated from the neck most of the blood supply to the head is completely destroyed which will result in severe damage. "The aim should be to avoid the necessity of an open operation." In general, the more radical the surgical procedure the poorer the end result.

Osteotomy has been performed in an effort to correct deformity of the leg. This may be either subtrochanteric, transtrochanteric or coneiform osteotomy of the neck. In the latter case great care must be taken to avoid destruction of the blood supply to the head, running in the capsule and synovial covering of the lower margin of the neck. Kleinberg and Buchman (18) reported good results from resection of the epiphyseal plate. Compere reported 14 cases of hips in which a wedge osteotomy of the femoral neck was done and the head fixed to the neck by means of multiple threaded wires. The average follow-up period was 2 years. One patient developed aseptic necrosis of the head, and one patient with bilateral slipping developed ankylosis in both hips. The remainder of the hips showed good results. He advocated a minimum of trauma and emphasized placing the head in a valgus position in relation to the neck before inserting the threaded wires.

Sudden acute slipping. If patients are seen early after the occurrence of acute slipping, the treatment of choice is gentle careful manipulation followed by immobilization, as the epiphysis is loose and may be maneuvered back into position. If not seen until repair has begun and malunion has occurred, the problem becomes the same as in the case of advanced, gradual slipping.

Old residual cases. In these cases ossification has been completed in a position of malunion of greater or less degree. Various reconstructive procedures have been performed, the results of which have been generally poor. Conservative palliative therapy is probably the method of choice.

Assessing the value of different methods of treatment from reports in the literature is somewhat difficult as there is a lack of uniformity in reporting. In some instances the duration of the lesion was not reported prior to treatment, in

others the follow-up period was too short, and in still others the degree of slipping was not given. Pomeranz and Sloane (40) have shown that deformity of the head and acetabulum with painful hips may appear as late as 5 years after apparently successful treatment. Many have reported a combination of several forms of therapy and in some cases it was simply stated that surgery was performed without specifying the procedure.

SUMMARY

Slipping of the capital femoral epiphysis is a condition which occurs during adolescence, probably comprising the most common cause of hip disability with onset in this age group. It is more common in males, with a ratio of 3 to 1 and coincident with the peak of adolescence, appearing somewhat later in males than in females. It occurs most commonly in the "overgrown," obese child or in the unusually tall child who has had a rapid growth in height.

The etiology has not been proved but probably the condition is due to an interaction of many factors, including anatomical changes at the joint at this period rendering it more susceptible poorly understood endocrine changes which may contribute to softening of the cartilage junction too rapid growth possible chemical imbalances and to other changes at adolescence which may in these patients be exaggerated beyond the normal. Trauma is usually the immediate cause of slipping.

The treatment is varied but its success depends upon the early recognition of the disease. These cases are rarely admitted to the hospital with a correct diagnosis. Our aim must be toward the education of all physicians who see patients of this age group, to consider this diagnosis, to recognize early slight physical signs and roentgen changes by careful comparison of the two hips, and to consider these patients as emergencies, instituting immediate treatment, to be continued with no lapse until closure of the epiphysis occurs and firm bony union is established between the head and neck of the femur.

3 cm. in diameter that occupied the lateral two-thirds of the right supraorbital ridge and pushed the eyeball down and in. An uneventful postoperative course followed its removal. The specimen was pathologically diagnosed as a chronic granuloma sequel to organization of an old hematoma.

The second case was that of a chauffeur aged 44. In 1934 he was struck on the left temporal region near the orbit. In 1946 he noted a swelling about the left eye, proptosis and diplopia, and a mass could be felt in the upper outer corner of the orbit. X ray examination showed a concentric, expanding lesion with rarefaction of the left frontal bone. At operation the affected bone which included the orbital margin the superior orbital plate and the floor of the anterior fossa, was removed. The dead space was filled with fibrin foam and the wound was closed. A month later the fronto-orbital defect was repaired with a tantalum cranioplasty. In the final examination vision was R. 20/20 and L. 20/30 left hypophoria of 4 prism diopters no exophthalmos and no ocular complaints.

Radiologically the post traumatic granuloma simulates any osteolytic lesion involving the frontal bone. Surgically they are cured by radical therapy. Pathologically, the essential lesion is a chronic granuloma composed of granulation tissue containing abundant hematogenous pigment, multinucleated giant cells cholesterol crystals many fat laden phagocytes and a variable degree of fibrosis. When a hematoma occurs in a bone the broken down blood may act as a foreign body with a consequent slow steady reaction over several years.

Removal of an Orbital Tumor through the Inferior Route with Kuhn-Szymanowski Repair of Ectropion. ALSTON CALLAHAN *South. M. J.*, 1948 41: 790.

A tumor mass that can be palpated over the infraorbital rim is best removed through an incision over the infraorbital rim and this method was used in the following case.

A woman aged 68 had noted proptosis of the left eye over a period of 27 years and in the last year the eye had become red and painful with profuse discharge and totally blind. Deep palpation between the eye and the infraorbital rim revealed a firm mass. An incision was made across the lateral half of the left lower lid and the orbital septum was then divided care being taken to avoid injury to the lateral can thus the infraorbital nerve and vessels and the origin of the inferior oblique muscle. The tumor was removed by finger dissection without injury to the ocular muscles and measured 3 cm. in diameter. The eye then returned to its normal position. The orbital septum was closed with chromic catgut, and the skin was closed with silk. Microscopic examination of the tumor proved it to be a hemangioma. Ectropion of the lower lid persisted and was corrected 6 months later by the classic Kuhn-Szymanowski operation.

Clinical Course of Glaucoma ADOLPH POSNER AND ABRAHAM SCHLOSSMAN *Am. J. Ophth.*, 1948, 31: 915

The present study is a correlation of 474 cases of glaucoma from private practice. In 373 patients the condition was primary. One hundred and fifty-eight patients have been followed for 5 years or longer. There were 71 eyes with acute congestive glaucoma, 140 eyes with chronic congestive glaucoma and 422 eyes with chronic simple glaucoma.

The authors attempt to consider the problem from a purely clinical point of view. Comparison of an isolated case of acute congestive glaucoma in which cure has been effected by surgical treatment, with a case of asymptomatic chronic simple glaucoma in which the tension is within normal limits or only slightly elevated, would seem to indicate that these are two separate diseases. However the authors state that analysis of a large number of cases invariably reveals gradations in the symptomatology and course to such an extent that a sharp line of demarcation cannot be drawn at any point in the series. Furthermore there is a mixed group of cases in which one may find either a congestive glaucoma in one eye and a chronic simple glaucoma in the other eye or a chronic simple glaucoma with acute exacerbations in one or both eyes. Additional evidence for assuming a unitary concept of primary glaucoma is found in a study of hereditary cases. In the same family tree one may find examples of congestive and chronic simple glaucoma.

Glaucoma should be regarded as a constitutional disease in the sense of a dysfunction of the central regulatory mechanism of the autonomic nervous system similar to the metabolic disorders such as diabetes hypertension and obesity. It is possible that this dysfunction constitutes the primary or at least the predisposing cause while the various anatomic and physicochemical conditions of the eye are modifying or precipitating factors. The fact that congestive glaucoma occurs in a small percentage of eyes with narrow angles and that this disease may also occur in eyes with wide angles tends to indicate that the angle plays a secondary role in the etiology of the disease.

The authors believe that although tension undoubtedly plays an important role in glaucoma there may be other factors which contribute to the cause of the disease. The following possibilities are suggested: (1) disturbance of the central autonomic nervous system (may include psychosomatic factors) (2) vasomotor instability (3) hereditary factors (4) arteriosclerosis (either general or local) (5) blood pressure (6) metabolic disturbances (diabetes, obesity endocrine) (7) relation of intraocular to intraocular pressure (8) degenerative changes in the nervous tissue (a) lacunary degeneration in the brain and nerve (b) Schnabel's cavernous atrophy and (c) local factors (a) anatomic (Schnabel's canal chamber angle retinal circulation choroid and so forth) (b) nutritional (c) congenital, and (d) physicochemical factors such as increased

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Nature of Aqueous Humor. SIR STEWART DUKES-ELDER. *J. Am. M. Ass.* 948, 137-138.

Though the aqueous cannot be completely described by the mathematics of dialysis, it is certainly not, in the generally accepted sense of the word, a secretion. Cogan and Kinsey using heavy water as a tracer have shown a free two-way transference of water between blood and the intraocular fluids, and conclude that the water in the aqueous is renewed every 3 minutes. Friedenwald finds the current in Schlemm's canal is 1 to 3 cm. per minute and suggests a unidirectional permeability in the ciliary body through differences in oxidation reduction potential maintained by enzyme systems.

The experimental fact remains that the concentration of ions in the aqueous approaches a dialysate even more than other undoubtedly dialysates such as ascitic fluid. Slight deviations are susceptible of explanation. For example the change in carbon dioxide tension accounts for a difference of 1.5 per cent between the plasma chloride concentrations of arterial and venous blood.

The glucose in the aqueous is less than that of the blood by the amount utilized in the metabolism of lens and retina. It rises in the aphakic eye. Different sugars enter the aqueous in proportion to the size of the molecules. The disaccharide sucrose penetrates much more slowly than glucose and the trisaccharide, raffinose not at all.

Observation of radioactive isotopes shows that the most rapid entry into the anterior chamber is through the iris. Glucose penetrates the posterior segment at only one third the rate at which it reaches the anterior chamber, sucrose at one-seventeenth. The iris acts apparently like an inert diffusing membrane while the membrane in the posterior segment seems more selective.

Urea, creatinine, alanine and glycine enter the eye more slowly than the larger molecule sugars. The blood-aqueous barrier is individualistic, and each constituent is treated in characteristic way.

There are then two mechanisms—a simple traffic through the iris mainly into the anterior chamber and a more discriminating one in the posterior segment.

Intravitreal Streptomycin: Its Toxicity and Diffusion. P. A. G. REINER, I. C. MICHALSON, R. J. W. REES, AND J. M. ROBSON. *Br. J. Ophth.* 948, 3449.

The author injected streptomycin subconjunctivally and intravitreally in a series of rabbits' eyes and found

1 Streptomycin injected into the vitreous of rabbits' eyes was diffused slowly throughout the eye, but had a deleterious effect on the retina. This was seen grossly and histologically.

2 Streptomycin injected subconjunctivally was not toxic to the eye but diffused rapidly out of the ocular tissue.

EARL H. MIERZ, M.D.

Craterlike Holes in the Optic Disc. EMANUEL ROSEN. *Br. J. Ophth.* 948, 331-365.

The author presents 7 cases of craterlike holes in the optic disc. He warns against confusing the diagnosis with glaucoma, since some patients have field defects, iris atrophy and pupillary inequalities. The cause for these pits is not known but it is possible that they are of congenital origin.

EARL H. MIERZ, M.D.

The Treatment of Severe Infected Corneal Ulcers by Subconjunctival Injection of Penicillin Twice Daily without Hospitalization; with a Short Review of Other Methods. KAMEL REIK. *Br. J. Ophth.* 948, 31-497.

The author presents a method of using penicillin subconjunctivally, twice a day 10,000 units at a time in 0.5 c.c. of 1 per cent novocain solution for the treatment of corneal ulcers. The treatment was usually completed in a period of 5 days with excellent results.

This treatment was more practical, more efficient and more economical than the intramuscular use. Instillation method, or subconjunctival injection every 4 to 6 hours.

The use of penicillin was then compared with older methods of treatment and found to be much better.

EARL H. MIERZ, M.D.

Post Traumatic Granuloma of the Orbit. G. STUART RAMSEY, H. WYATT LAWS, J. E. FRUTKIN and HAROLD ELLIOTT. *Cas. M. Ass. J.* 948, 59-106.

Two cases of post traumatic granuloma of the bony orbit, simulating tumor are presented. A third case shows the identical pathological process in a rib. The literature contains only two previous instances of this rare condition.

The first case was that of a laborer 57 years of age. In 1943 his right supraorbital area struck the pavement in an automobile accident, with a proptosis of the right eye. X-ray examination showed a comminuted fracture of the margin of the right orbital fossa. Seven months later a tumor mass was noted fixed to the right frontal bone. The corrected vision was R. 20/35 L. 20/30 exophthalmometer, R. 19 mm., L. 12 mm., R. hypophoria of 5 prism diopters. A right supraorbital craniotomy revealed a tumor

United States Army general hospitals in England more patients were seen with blast injury of the ears than with any other injury or disease.

The studies reported here were made on 100 patients with acoustic trauma, admitted to this general hospital in the first 6 months after invasion of the European Continent in June, 1944. These were the first 100 patients who could be adequately studied although many others were seen and treated during this period. The patients not included in this series were eliminated because of other injuries which prevented audiometric examination or because they were under observation for too short a time. Many of these patients were seen within 1 week of injury but none before the third day. Some of them remained under observation for as long as 3 months. The findings in these men were deafness, tinnitus, interstitial hemorrhage and rupture of the tympanic membrane and acute suppurative otitis media.

Whispered voice tests and audiometric studies were done on all these patients and were repeated at intervals to follow their progress. A rough determination of the acuity of hearing for speech can be obtained by the whispered voice test. Audiometry is a much more accurate method evaluating and following changes in the loss of hearing for sound. This is borne out by a comparison of the findings by audiometry with those obtained by whispered voice and tuning fork tests.

A history of aural disease which existed prior to the blast injury was given by 23 of these patients. Six had total unilateral deafness, 11 had partial deafness and 9 had healed acute suppurative otitis media. Four gave a history of both deafness and previous aural suppuration.

Seventy per cent of the injuries were caused by high explosive shells. In some cases there had been repeated exposure to blast and heavy firing but no acute injury occurred.

The impairment of hearing was severe in 14 patients, moderate in 15 and slight in 71.

Prophylaxis. No satisfactory mechanical method of protecting the ears against blast injuries was in common use in World War II. None of the patients whose cases are reported used any means of protection. The reasons given for this neglect were summed up by Guild who stated that (1) dry cotton is ineffective in stopping even moderately intense detonation waves, and that (2) cotton soaked with oil or petrolatum and solid obturators are entirely unsuitable for use by those whose duties require that they be able to hear ordinary sounds well at all times.

Tinnitus. Inflation of the eustachian tube did not influence the tinnitus. No specific therapy was used in treating patients for this symptom.

Rupture of the tympanic membrane. Most of the smaller perforations healed without intervention. Occasionally it was necessary to stimulate the margins of the perforation by mild scrubbing or by applying 10 per cent silver nitrate to the margins of the perforation to stimulate healing. Marginal perforations appeared to close more slowly than the others.

Large perforations with damage of the ossicles showed no tendency to heal. Most of the perforations that healed did so in less than 1 month.

Acute suppurative otitis media. The prophylactic treatment impressed on the medical officers in the forward areas was the preventing of contamination of the ears by absolute avoidance of syringing or of applying drops to the ears. Not one of the patients in this series received injudicious aural therapy in the forward areas. The patients themselves had to be instructed not to contaminate their ears. In the presence of a dry traumatic perforation none of the sulfonamide powders was insufflated because it was felt that there was no advantage to be gained. Many of the patients had other injuries and were treated with sulfadiazine or penicillin or both a short time after being injured.

The active treatment was a daily cleansing of the infected ear with hydrogen peroxide and dry wipes, followed by instillation of one of the following local medicaments: sulfathiazole sodium solution (5 per cent), penicillin solution (containing 1000 units per cubic centimeter), sulfanilamide powder or 2 per cent boric acid in alcohol. Sulfadiazine or penicillin was frequently used systemically in addition to the local therapy. These infections responded rapidly to treatment. In none of the patients did acute mastoiditis or other complications develop.

Thirteen case histories are reported accompanied by their audiometer charts. JOHN F. DELZER, M.D.

A Newer Concept of the Management of Otitogenic Infection. MERRILL B. HAYES and C. FREEMONT HALL. *Arch. Otolaryng.*, Chic. 1948 47: 289.

The authors believe that otologic infections in temperate zones can be divided into a winter phase during which gram positive organisms predominate, and a summer phase during which gram negative organisms predominate as the infecting agent. In the former type treatment has been practiced successfully with penicillin and other antibiotics. In the treatment of the latter difficulty has been encountered by many and in the past has not been successful. In an attempt to improve the treatment of gram negative otologic infections the authors studied a group of 100 cases exhibiting acute otitis media, chronic suppurative otitis media and otitis externa. In many of these, particularly in patients with otitis externa, the usual forms of treatment brought about the disappearance from the culture, of all bacteria except from the gram negative *Pseudomonas aeruginosa* (*Bacillus pyocyaneus*) and *Bacillus proteus* types.

After trying many compounds the authors found in the early part of their study that the most effective compound against the gram negative bacteria was monobromosaligenin. Later dibromosalicylaldehyde was found to be equally as efficacious as monobromosaligenin and, in addition this drug was active against fungi. Dibromosalicylaldehyde was considered the drug of choice. The two substances were used locally as a powder or ointment, or in solu-

capillary permeability and diminution in cholinergic substance.

In 60 per cent of the cases of primary glaucoma the onset occurred between 41 and 60 years of age. Fifty patients showed hereditary tendencies. The pedigrees studied exhibited dominant inheritance.

MICHEL LOUVALIAN, M.D.

Green Spectacles Prescribed in Glaucoma. R. B. ZARETSKY. *Am. J. Ophth.* 948, 31 935.

It has been shown that the illumination of an eye with green light resulted in the lowering of the intraocular pressure in the other eye this effect being especially pronounced in glaucomatous eyes. It seemed natural, therefore, to test the use of green spectacles as a means tending to reduce intraocular pressure. Experiments were carried out on 19 subjects, with a period of observation varying between 15 to 15 days for hospitalized patients and 30 or more days for out patients.

From an analysis of curves obtained, it may be said that notwithstanding the total suspension of pilocarpine medication the intraocular pressure showed a pronounced tendency to decrease in patients wearing green spectacles the range of fluctuations of intraocular pressure during the day was likewise found to decrease. An appreciable effect was obtained when the use of green spectacles was combined with the administration of very small doses of pilocarpine (0.5 per cent solution twice daily). The decrease in intraocular pressure was much more striking however in certain cases in which the use of green spectacles was combined with small doses of adrenalin.

Green light, while acting upon the color receptor of our vision produces a definite rearrangement in the vegetative nervous system, thus also affecting the neurovascular apparatus of the eye. We may assume that the amounts of acetylcholine and sympathin in the eye are different according to whether the eye is exposed to red or green light.

The encouraging results of the experiments cause the author to believe that the use of green spectacles may in certain forms of glaucoma, prove a helpful therapeutic procedure especially if prescribed along with small doses of adrenalin or pilocarpine.

MICHEL LOUVALIAN, M.D.

Beta Irradiation in Glaucoma. GEORGE M. HAIR, L. A. BREITHEIM, and AXLETA BARKER. *Am. J. Ophth.* 1943, 31 945.

The authors conducted a series of experiments in which beta irradiation was applied to the ciliary body of rabbits in varying amounts over varying periods of time in an endeavor to determine the practicality of treating glaucoma by obliteration of the vascular supply of the ciliary body with the objective of bringing about a decrease in the production of intraocular fluid. The experiments reported were planned in the light of changes in the vascular endothelium, leading to proliferation and various degrees of occlusion of the lumen which have been reported

after beta radiation, and which are most marked in the endothelium. While vascular changes were achieved in the majority of cases, damage to the lens also resulted in almost every instance in which the desired changes were accomplished.

The proposed method seems theoretically sound, however to make it practical, a dosage of radium must be established which will bring about the desired changes in the ciliary body without damaging the lens at the same time. Probably this objective could be accomplished if an applicator were available which would permit the emanation of beta rays but would screen out gamma rays.

A clinical case is presented in which irradiation was employed because the state of the eye was already practically hopeless. Apparently the treatment has produced no ill effects, but the therapeutic results are still inconclusive.

MICHEL LOUVALIAN, M.D.

Operative Failures for Chronic Glaucoma. BERT TAYLOR PAYNE. *Am. J. Ophth.* 943, 3 1965.

A study of eyes removed after operative failures for chronic simple glaucoma shows that ideal surgical relief has not been devised so far as the laboratory is concerned. The examination of approximately 100 eyes operated upon for glaucoma at the New York Eye and Ear Infirmary showed at least three characteristics: (1) adhesions between the iris and the cornea, (2) closure of new filtration channels with fibrosis and (3) inflammation of the uvea. Synechia between the anterior surface of the iris and the posterior surface of the cornea are composed of such dense connective tissue that permanent separation by operation is almost impossible. The artificial filtration channel, or channels become closed by the proliferation of connective tissue despite an iris inclusion in the operative wound. Progressive iridocyclitis usually requires enucleation. Operations for glaucoma performed on globes sent to the laboratory are iridectomy, iridencleisis and trephination.

Common pathologic changes are present in eyes removed after operative failures for chronic simple glaucoma. A comparison of the histology of normal eyes with that of chronic simple glaucoma may reveal the causes of operative failures. Failure of iridectomy may be due to the persistence of synechia and to failure to remove the iris at its roots. In iris-inclusion operations the iris itself may produce closure and in trephinations closure may occur as the result of fibrotic and inflammatory changes.

EAR

Blast Injuries of the Ears. ORIEL FREEDMAN. *Arch. Otolaryng.* 943, 47 47

The concussion or blast produced by the high explosives used in modern warfare is greatly injurious to the auditory apparatus. This fact quickly became obvious to an otolaryngologist treating battle casualties in World War II. On service in one of the

PHARYNX

The Uvula: Its Structure and Function and Its Importance. GEORGE S. RICHARDSON and E. MARKEY PULLER *Arch. Otolary.*, Chic., 1948, 47: 379

On the whole there is no structure within the confines of the body so little understood and so often abused and maligned as the uvula. This structure's function appears in the literature in only the briefest fashion. The uvula has been classed with vestigial structures such as the vermiform appendix.

In the present article, the authors delve deeply into the anatomy of the nose and soft palate as related to the uvula. This is illustrated by 4 anatomical drawings by one of the authors.

The functions of the uvula are summarized as follows:

It massages and moistens the cellular structure of the posterior pharyngeal wall; it aids in the removing of material from the posterior pharyngeal wall and in the passing of this material downward to the hypopharynx and the base of the tongue; it serves as a transfer organ to bridge the deficiency between the velum and the posterior pharyngeal wall as secretion moves from the midline above and anteriorly to the midline posteriorly; it is a valuable aid in preventing middle ear disease in children by participating in the preservation of normal pharyngeal arches; the uvula prevents pharyngitis sicca with subsequent drying of the eustachian orifices as might be expected with a high arch on one side or with a fibrous straight line contracture; it is the warning flag of the pharynx in many instances; it prevents rhinolalia aperta in successful tonsillectomy and is a valuable adjunct to voice control, possibly as a midline buttress, particularly in singers. This function is of little value in the speaking ranges apart from preventing unpleasant qualities; a uvula deviating to one or the other side may indicate a weakness of the accessory nerve on the opposite side.

The conclusions reached are as follows:

The uvula is a valuable means of preserving and detecting nasopharyngeal health and change. It should not be traumatized needlessly nor should it be subjected to operation unless a definite syndrome traceable to it is evidenced.

More must be known about the eustachian tube and its nasopharyngeal orifice before one becomes willing to sacrifice a uvula, or to class it as a vestigial

remnant. To ignore an edematous uvula is as negligent as to ignore chronic hoarseness without ascertaining the state of the vocal cords by viewing the anterior commissure in indirect laryngoscopy.

Case histories are presented to illustrate certain points in the text, such as the influence of the uvula on the health of the nasopharynx and its influence in reinforcing the soft palate in voice control.

NECK

Lymphadenoid Goiter. H. M. GOLDBERG and J. DAVSON *Brit. J. Surg.* 1948, 36: 41

The authors endeavored to find out, first, whether it is possible to differentiate clearly between thyrotoxicosis or simple goiter with lymphocytic infiltration on the one hand and lymphadenoid goiter on the other and, secondly, to determine whether a study of the relationship between the two conditions can throw any light on the etiology and development of lymphadenoid goiter.

They conclude that no sharp dividing line can be drawn on histological grounds between toxic goiter with lymphoid infiltration and established lymphadenoid goiter; the differences appear to be essentially ones of degree.

They further believe their study has shown that focal changes histologically indistinguishable from those seen in the various stages of lymphadenoid goiter can very frequently be found in the rim of thyroid tissue immediately surrounding an area of adenomatous hyperplasia, and also immediately beneath the fibrous tissue capsule of the gland. Both locations are sites where compression of thyroid acini would be liable to occur as the result of increase in size of part or whole of the gland. They believe it is reasonable to conclude that the changes are secondary to local ischemia, and it is suggested that the widespread changes occurring in lymphadenoid goiter are similarly due to ischemia, probably a relative ischemia due to the blood supply being insufficient to meet the increased demands created by the stimulation of the thyroid epithelium by the thyrotropic hormone. The fact that the changes are never seen inside an area of adenomatous hyperplasia, which for its growth and maintenance depends on an adequate blood supply, is considered further support for the ischemic causation of the lymphadenoid changes.

Bone-Dust Free Lempert Fenestra Nov-Ovals: A New Evolutionary Development of the Surgical Treatment of Clinical Otosclerosis. JORIS LEMPERT. *Arch. Otolaryng.* 1948, 47: 280.

In the surgical treatment of clinical otosclerosis, bone sand and bone splinters have always been the by-products of fenestrating the bone labyrinthine capsule with the electrically driven burr. When the final endosteal bony layer in this operation is fractured inward, the author believes that bone dust and splinters are almost invariably lost within the perilymphatic space and their presence there enhances the tendency to osteogenesis that exists at the fenestral rim. Failure to remove these particles, according to the author, may lead to postoperative closure of the fistula. However, he points out that attempts at removing the bone splinters may inadvertently involve injury to either the perilymphatic trabecular blood vessels, with resultant hemorrhage in the perilymphatic space, or to the endolymphatic labyrinth.

At the time of re-operation in cases in which the gain in hearing was not maintained, the author observed new bone formation involving the fenestral rim or involving both the fenestral rim and the perilymphatic space. He reasoned hypothetically that perhaps the perilymphatic endosteal osteogenic process which he observed in the human subject had been initiated by bone fragments that found their way unnoticed into the perilymphatic space. In order to avoid such an occurrence, a technique for fenestrating the surgical dome of the vestibule without creating bone splinters and dust was evolved. This is done by removing the bony surgical dome of the vestibule until only the endosteal bony layer remains. An incision is then made through the endosteal bone to outline the fistula. The cap thus created is everted and removed intact, exposing the endolymphatic labyrinth. Finally the fenestral rim is burnished with a lead burr. In this way the author believes, injury to the endolymphatic labyrinth and perilymphatic trabeculae is avoided, and the formation of bone dust and splinters is also avoided.

Ten figures of microscopic sections, and a number of drawings are included.

Chorda Tympani Nerve Graft: A Preliminary Report of a New Technique Used in Surgical Penetration of the Labyrinth. SAMUEL ROSEN. *Arch. Otolaryng.* 1948, 47: 428.

Otolaryngists are indebted to Lempert for the first practical one-stage technique for the surgical treatment of clinical otosclerosis. However, significant numbers of failures continue to be a challenge to the surgical techniques developed therefrom. The two most important causes of failure appear to be bony or fibrotic closure of the fenestra and postoperative membranous labyrinthitis of varying degrees. Anal-

ysis of these factors had led Lempert and Shambaugh to introduce modifications of the fenestration technique in an attempt to increase the percentage of successful cases. Possibly the amount of auditory improvement could be increased to an even higher level in successful cases if the degree and the duration of the postoperative labyrinthitis could be diminished.

The chorda tympani nerve is liberated from its attachment to the facial nerve and is placed over the fenestra to protect the membranous labyrinth and the perilymphatic space from the untoward effects of blood and inflammatory products coming mostly from the overlying tympanomeatal flap. The chorda seems eminently suited to play the role of protective barrier to the delicate labyrinth since it withstands successfully all degrees of acute purulent otitis media to which it is exposed. Taste on the anterior two-thirds of the tongue is not affected in acute purulent otitis media. It is interesting to note that in its tympanic course the chorda tympani nerve is covered with mucous membrane.

A myringotomy knife is inserted between the chorda tympani nerve and the inner surface of the tympanic membrane. The blunt edge of the knife is swept upward beyond the point at which the chorda is attached to the neck of the malleus. In a similar manner the myringotomy knife is swept downward to the region where the chorda enters its bony canal. The chorda, covered by mucosa, is then grasped with a jeweler's tweezers about 3 to 5 mm below the malleus. Traction upward with the tweezers is continued until the chorda is pulled out of its bony canal. The free length of the chorda is then placed safely in the tympanum until the fenestra nov-ovalla is completed. Then the chorda is placed over the middle of the length of the fenestra from above downward. In this position the chorda tympani lies on the delicate membranous labyrinth with only the very slightest perilymphatic space visible on each side of the nerve. As the chorda is being pulled out of its canal, great care is necessary to avoid tearing it before its free end is long enough to reach and cover the fenestra. When the chorda has been completely evulsed from its attachment to the facial nerve it may be long enough to be looped back up alongside and parallel to the descending portion of the chorda. This double length of chorda tympani covers the fenestra completely. The tympanomeatal flap is then put in place.

Eight cases are reported. Within 2 weeks after the operation, all patients had a decibel loss of 25 or less. Hearing continued to improve rapidly, and by the fifth week following operation the majority had a decibel loss of 15 or less. This level of hearing has been maintained or improved to date.

Thus far osteogenic closure of the fenestra has not occurred in any case. It is too early to predict to what degree, if any the chorda tympani graft may succeed in preventing osteogenesis.

The article is illustrated with 4 figures and 3 tables.

number of British and American authors since this surgical procedure was first used by Moniz and Lima, in 1936. They perfected 7 different types of bilateral incision in the frontal lobes made by an approach through the temporal fossa. The opening in the skull is situated 3 cm behind the lateral orbital margin and 3 cm above the zygoma, allowing identification of the area of the brain exposed by the position of the Sylvian vessels. The authors use the MacGregor Crumlieu leucotome and claim to be able to perform smaller and more selective leucotomies. They state that their upper incision of the white matter leads to improvement in patients with psychomotor activity, and suggest orbital leucotomy in the passive and emotional states. Cushing's Disease with a Hyperplastic Basophil Cell Tumor of the Hypophysis (Maladie de Cushing avec tumeur hyperplasique a cellules basophiles de l'hypophyse) HENRI METZGER, LOUIS FROMLING, and MARCOURITE MESCHIMOSER. *Ann endocr* Par 1948 9 35

This article is really a case report of a 52 year old single woman with symptoms pointing to a Cushing syndrome in whom a complete postmortem examination was carried out. There was a small tumor in the anterior lobe of the pituitary gland which was composed principally of basophil cells. The patient had menstruated regularly up to the age of 50 years. She was small in stature and had a round hirsute face with bilateral exophthalmos. She had a heavy abdomen and thin tapering extremities. Her chief complaint was cramps in the legs when walking. The blood pressure was 220/180 and the electrocardiogram showed there was severe left ventricular strain. There was some kyphosis in the thoracic spine. The posterior clinoid processes were destroyed. In addition to the findings in the hypophysis there was evidence in the kidneys of a malignant nephrosclerosis.

The author distinguishes between Cushing's disease and Cushing's syndrome. The syndrome can be produced by extrapituitary lesions such as adrenocortical tumors or tumors of the thymus or ovary. The bibliography is very small and does not entirely cover the work of the authors quoted.

SPINAL CORD AND ITS COVERINGS

A Contribution to the Knowledge of the Conus and Filum Ependymoma. LENHART ZETTERGREN. *Upsala läk fören. förh* 1948, 1 11

Quoting reports from the Mayo Clinic, the author states that approximately every fifth tumor of the central nervous system is a spinal cord neoplasm and that among a group of 557 intraspinal tumors 64 were intramedullary. Of these 64 33 were ependymomas or ependymoblastomas and approximately 50 per cent of them were located in the filum terminale in the lowermost portion of the true spinal cord. Two illustrative case histories are given. Quoting Kernohan and others, he lists these tumors

under several types—epithelial, myxopapillary and cellular types of ependymomas.

The clinical symptoms of tumors in this part of the root or conus are characterized by pains of a sciatic type, weakness and numbness in the lower extremities and incontinence of urine. The symptoms usually developing in that order. He believes that myelography is extremely valuable in the topographical location of the tumor. JOHN MARTIN M D

Diagnostic Puncture of Intervertebral Discs in Sciatica. K. LINDBLOM. *Acta orthop scand* 1948 17 231.

The author's rather unorthodox procedure described in this article consists of the fluoroscopic control of the needle point when a spinal puncture needle is passed through the interspinous space through the dural space on through the posterior longitudinal ligament, and into the intervertebral space where a ruptured disc is suspected to be present. Some such contrast medium as diodrast is injected. By means of this method he has been able to demonstrate the actual disruption of the disc between the vertebral bodies showing the direction and nature of the posterior or posterolateral protrusion through the canal of rupture. He states that so far the indication for a diagnostic disc puncture is long standing sciatica, which was not improved by conservative treatment and which had been myelographed by a broadil without definite localization of the disc protrusion. This procedure was first done on cadavers and the excellent visualization of disc lesions on such specimens led to applying the same procedure to the living subject.

Apparently the author does not believe that the clinical signs and myelography, although corresponding to the localization of the level of the lesion are 100 per cent reliable evidence. The possibility of injury to the roots of the cauda equina by this procedure is only briefly mentioned by the author.

JOHN MARTIN M D

The Bladder in Spinal Cord Injuries (La vessie des traumatismes médullaires) R. CANNLON and G. PEL. *OT J sual méd.*, Par 1948 54, 101

After reviewing the anatomy of the bladder the authors discuss the physiology of micturition. They recognize a center of controlled micturition regulating the striated muscles, a center of automatic micturition in the lumbosacral segment of the cord regulating the nonstriated bladder musculature, and a center of automatic micturition within the bladder wall. In the infant, urination is produced by a reflex mechanism involving the automatic center only while in the adult the desire to urinate becomes conscious, the automatic center is controlled consciously by the higher center which also activates the striated bladder muscles. Wilful urination is dependent on the action of the striated sphincter muscle. The automatic system regulates the action of the detrusor muscle responsible for the expulsion of the vesical content and also of the nonstriated internal

SURGERY OF THE NERVOUS SYSTEM

Tantalum in the Repair of Traumatic Skull Defects.
WALFOLLE LEWIS, M. F. GRAHAM, and G. B. NORTH-
COTT. *Brit. J. Surg.* 1948, 36, 26.

A comprehensive review is given of 128 cases in which tantalum cranioplasty was performed and a 2 year follow-up on 124 of these patients is included. The indications for repair the preparation of the plate, and the operative technique are considered for each type of case however, the discussion of the results obtained is perhaps of greatest interest.

Uncomplicated postoperative convalescence was observed in 110 of the 128 patients, with no immediate mortality. Persistent collections of spinal fluid beneath the scalp were noted in 3 patients, pressure necrosis with scalp infection occurred in 1 patient, coliform meningitis developed in 1 and in 3 patients with associated frontal defects, the cosmetic effect was poor. Ten patients developed epilepsy within 2 weeks after operation, half of whom had had pre-operative seizures.

Late results were judged primarily on the basis of answers 124 patients gave to a questionnaire, or on the basis of a supplementary letter from the patient's physician. Three patients died within the follow-up period. One had developed status epilepticus and died shortly after the removal of the plate, a second presumably died of recurrent meningitis in a mental hospital 1 year after plating, and a third succumbed to pneumonia unassociated with his cranioplasty.

Removal of 11 plates had to be carried out. In 2 cases this was because of poor cosmetic results, 5 were removed because of infection and 4 because of intracranial complications. The authors point out that the one-stage preformed plate method has definite limitations in the frontal regions, for of the 68 patients with defects in this area, 8 were regarded as having an unsatisfactory result. Only 3 of these cases were thought to be complete failures, however. In all, only 7 per cent of the patients reported any local discomfort or pain as far as the plate itself was concerned.

Infection in the original wound had caused delayed healing in 31 patients in the series.

After evaluating these cases it was the authors' opinion that with proper chemotherapy repair of infected wounds can be safely carried out 3 months after final healing of the wound. The incidence of infective complications referable to the tantalum plate was 7 per cent but when the plate was related to a defect in the frontal sinus there was an additional 9 per cent risk in infection. Intracranial complications required removal of the plate in 4 cases. In one of these there was an underlying abscess in 3 others symptoms were due to hydrocephalus. In this latter group there was the sug-

gestion that tantalum in contact with the ventricular system may actually stimulate the production of cerebrospinal fluid hence close attention must be paid to repairing all dural tears or defects. Fifty-one of the patients had had convulsive seizures, and the only ones in this series who showed improvement in their epilepsy were those on whom an intracerebral operation had been performed in association with the cranioplasty. A very complete discussion of late sequelae is presented and numerous interesting cases are cited in detail.

RICHARD C. SCHNEIDER, M.D.

Differential Diagnosis of Tumors at the Cerebellar Isthmus. ANTONIO GONZALEZ REVILLA.
Bull. Johns H. Sp. H. Hosp. 1948, 83, 87.

The author presents a review of 203 tumors of the cerebellar isthmus observed at the Johns Hopkins Hospital, Baltimore from 1926-1945 and verified at operation. Seventy-eight per cent of these tumors were acoustic neuromas. The remainder were cholesteatomas, meningiomas, gliomas, abscesses and miscellaneous tumors such as sarcomas of the meninges, malignant melanomas and carotid body tumors. The relationship of angle tumors to pain similar to that present in idiopathic trigeminal neuralgia is discussed.

It was found that the meningiomas occurred in a higher age group than the acoustic neuromas, more commonly affected, and that radiographic erosion of the internal acoustic meatus is more rare in the presence of meningioma of the angle than when an acoustic neuroma is present.

Cholesteatomas are more apt to appear in a young age group, the duration of symptoms is longer and the resulting headaches are not as severe as those of an acoustic neuroma.

Acoustic neuromas are more likely to produce severe unilateral seventh and eighth nerve changes than do the gliomas, but differentiation between an angle neuroma and a glioma is frequently difficult.

The abscesses usually are accompanied by an occult history or the presence of a known pyogenic focus elsewhere in the body. Frequently Gradenigo's syndrome may precede the symptoms of an abscess in the angle.

The metastatic lesions are apt to occur in older individuals, the neurological symptoms are usually more widespread, and especially does the rather late appearance of the patient's difficulties exclude a tumor arising within the eighth nerve.

JOHN MARTIN, M.D.

The Operation of Prefrontal Leptocotomy. E. CUNNINGHAM DAX and E. J. RADLEY-SMITH. *Br. J. Surg.* 1948, 36, 74.

The authors describe the various approaches and techniques of prefrontal lobotomy devised by a

flowing. If residual urine is present, bladder neck resection may help. However in these cases renal function is easily disturbed and no method of treatment is satisfactory. Cystotomy must be performed if signs of kidney damage are present.

The most frequent urinary complications in paraplegics are cystitis and ascending and hematogenous pyelonephritis. They are often associated with bladder stones and are more frequent in bedridden patients. The G and M solutions may dissolve or reduce the volume of the calcium carbonate and calcium phosphate calculi. However the larger calculi must be removed surgically. Streptomycin may help when penicillin or the sulfonamides do not succeed, but it rarely stops an infection if a bladder stone or a suprapubic fistula is present. The prognosis of urinary infections in paraplegics remains poor.

GEORGE PERRET, M.D.

PERIPHERAL NERVES

Tensile Strength of Human Nerves: An Experimental Physical and Histologic Study. C. T. LIO, C. E. BENDA, AND F. H. LEWIS. *Arch. Neurol. Psychiat.* Chic., 1948, 59, 322.

These authors have performed a very useful function in publishing the results of their obviously carefully made experiments on the tensile strength of human nerves. Their material consists of 27 human nerves—3 sciatic, 4 ulnar, 7 tibial and 8 peroneal—which were removed from cadavers 6 to 12 hours after death when death was in no way related to any condition of the nerves.

The authors are aware of other optimistic reports concerning the stretch capability of human nerves but they feel that the important question is not when complete rupture occurs but at what force damage to single nerve fibers first appears and this they have demonstrated very well by means of a simple tensiometer. Their methods and statistics, neither of which are complicated, show that herniation of the nerve fibers through the sheath begins in the sciatic nerve at a 21 per cent stretch and in the peroneal nerve at 16 per cent. They demonstrated to their own satisfaction that the actual tension expressed in kilograms per square centimeter of the tested nerve, is not so good a guide to nerve damage as the actual percentage of stretch produced. One of the ulnar nerve specimens stretched 4.7 per cent under a tension of 15.3 kgm. per square centimeter and in this specimen two of the three main fascicles composing the nerve were ruptured while the third fascicle showed minor damage at different levels. The endoneurium is apparently less elastic than the perineurium and often is torn transversely together with the nerve fiber bundles. The endoneurium was torn at about 20 per cent stretch. Microscopic hemorrhages were frequently noted about the endoneurial vessels. The nerve fibers in most cases were observed to be completely interrupted when the nerve was stretched beyond 10 per cent. The myelin sheaths were frequently fragmented.

Apparently the axis cylinder and myelin are the least resistant to stretch, whereas blood vessels in the endoneurium and perineurium are more resistant. The authors believe therefore that no human peripheral nerve should be stretched more than 6 per cent of its length, beyond which point severe internal microscopic fracture occurs in various places. Under such conditions the degree of recovery will be greatly minimized. The significance of their findings is important in the repair of severe peripheral nerve lesions during which the effect of stretching may not be known to many surgeons. JOHN MARTIN, M.D.

Post Traumatic Ossification of the Peripheral Nerves. Histogenetic Study of Heterotopic Osseous Neoformations (Ossificazioni posttraumatiche dei nervi periferici. Studio sull'istogenesi delle neoformazioni ossee eterotopiche). LEONARDO GULI. *Chir. org. movim.* 1948, 32, 241.

The author presents 7 cases in which calcification developed in and about the cicatricial regions of an injured nerve. Microscopic studies were made of the removed osseous neoformations. Three of these patients had suffered injury to the sciatic nerve (1 with and 2 without associated fracture), 1 patient had an injury of the median nerve, 2 patients had suffered injury to the radial nerves without associated fracture and 1 patient had suffered an injury to the axillary nerve with associated fracture of the clavicle. The osseous processes were of no special significance as the nerve tissues themselves did not take part in the abnormal process of calcification and the newly formed bone was easily removed without any effect on the ultimate outcome of the case.

Microscopic study of the removed tissues demonstrated that the osseous tissues in each case were entirely independent of the neighboring bone apparently taking origin from the cicatricial changes between the ends of the injured nerve or from the tissues of the perineurium.

From his studies of the tissues in this group of cases the author is led to regard the theory of cellular new bone formation as postulated by Lenche and Polycard (wherein the lime salts are laid down directly within the meshes of the collagen fibers of the connective tissue without any participation on the part of the connective tissue cells themselves or cells derived from elsewhere in the body) as not adequately explaining all the findings observed in these cases. For the general process of osteogenesis the clarifications of S. Kromprecher (*Die Knochenbildung* G. Fischer, Jena, 1937) are accepted as embodying the classical opinions on the subject. With this theory the process of ossification is mediated by special cells (reserve cells) which normally lie dormant among the connective tissue cells until roused to form osteoblasts by the stimulus of the injury or of some other unknown factor. However Kromprecher's clarifications are not accepted in full. It is the author's impression that these osteoblasts arise as a transmutation of young connective cells.

JOHN W. BRENNAN, M.D.

sphincter fibers responsible for urinary retention. The innervation of the evacuation musculature is parasympathetic and is transmitted through the nervi erigentes. The sphincter tone is sympathetic and secondary and is supplied through the two branches of the hypogastric plexus fibers originating in the sacral ganglia and accompanying the nerve erigentes and periauricular sympathetic fibers. The afferent sensory pathway of the micturition reflex is also formed by the parasympathetic nervi erigentes and their posterior roots. Thus the parasympathetic system controls sensation and emptying of the bladder and the sympathetic system regulates bladder continence and ejaculation and also has a trophic and a secondary extraperitoneal sensory function.

The paralyzed bladder of the paraplegic shows retention during the initial period of medullary inhibition or spinal shock, and in the later phase of spastic paralysis it develops reflex contractions which become very useful in the development of automatic micturition. The authors state that in the initial flaccid stage the muscles controlled by the automatic and voluntary centers are paralyzed while the sphincter tone controlled by the extramedullary ganglia of the sympathetic chain is not decreased but increased. The nonstriated sphincter musculature is therefore spastic and urinary retention results. The intravesical pressure increases and eventually overcomes the internal sphincter and produces passive incontinence because of overflow.

The classical treatment of the distended bladder by repeated catheterization or continuous drainage often results in vesical, urethral or periurethral infections, while early cystostomy does not allow complete drainage and may be responsible for infection due to urinary stagnation. Modern treatment consists of manual expression of the bladder contents. When not contraindicated by urethral obstructions or ruptures this method enhances the development of spontaneous contractions of the bladder and restoration of micturition. The bladder does not become infected. If this procedure is not practicable tidal drainage is the other method of choice. Various isotonic and antiseptic solutions may be used and introduced into the bladder at a rate of 60 drops per minute. The intravesical pressure can be adjusted to the tonicity of the bladder. The catheter should be changed every 6 days. When automatic micturition is established, tidal drainage should be discontinued if the residual urine is not more than 100 c.c. but continued if it is over that amount. By weekly cystometry recovering function of the bladder can be studied. The catheter can be removed if intravesical pressure of 25 mm. of mercury produces a contraction of the bladder.

Controlled micturition may be regained only in the cases of partial cord lesions. Complete cord transection results only in reflex urination. Tidal drainage is of no value in low cord lesions in which the bladder will remain atonic, or in cervical lesions. It is also contraindicated in urethral or prostatic infections or inflammations. When cystostomy is nec-

essary tidal drainage can be applied if the bladder opening is small. Occasionally tidal drainage must be replaced by two daily irrigations of the bladder through an indwelling catheter.

As soon as the paraplegic patient enters the spastic stage recovery of bladder function can be better evaluated. In partial cord sections nearly normal controlled micturition can be obtained provided half of the spinal cord is intact. In complete physiological or anatomical cord transection micturition becomes automatic if the lesion is above the medullary center of Budge in the lumbosacral segment of the cord. Although the afferent sensory pathways are paralyzed many patients have a sensation of fullness when the bladder is full. This sensation is transmitted by retroperitoneal sensory sympathetic fibers. The automatic urinary reflexes can be induced voluntarily by some patients by compressing the glans penis or pinching the internal aspect of the thigh. Thus, in accord with the site of the lesion and the intelligence of the patient, automatic micturition may be disciplined and controlled to a certain extent.

In cases of destruction of the conus medullaris or complete transection of the cauda equina, automatic micturition develops and results from the function of the ganglia within the bladder wall alone. The bladder and sphincter muscles become hypertrophic, the bladder content is reduced, the contractions are weak and frequent, and the residual urine is high. Complete transection of the cauda equina produces complete bladder atonia. Tidal drainage is useless in these cases as automatic function will never develop.

Under the title of vesicourethral dystonias, the authors describe numerous and frequent obstacles which disturb the recovery of micturition. The most common are changes in the muscle fibers which result from distention, infection, and spasticity. The loss of tone, the sclerosis and the hypertrophy of the muscle fibers are the frequent causes of difficulty in urination, pollakiuria with active incontinence and passive incontinence. In difficult urination there is often residual urine caused by increased resistance at the bladder neck. Various remedies have been suggested such as plastic muscle transposition, presacral neurectomies, section of the hypogastric nerves, and sacral sympathectomies but the simplest and most efficacious procedure is the transurethral bladder neck resection. Pollakiuria with active incontinence is produced by spasticity and hypertrophy of the detrusor muscle. The bladder content is small and there is residual urine. A small amount of urine added to the residue produces micturition and results in continuous incontinence. Section of some of the parasympathetic fibers (nervi erigentes) or anterior rhizotomy of the first and second sacral roots is the most logical method of treatment. The administration of scopalamine, vitamin B₁, and a high protein diet has also been recommended. Oftentimes good results can be obtained by transurethral neck resection followed by tidal drainage. In passive incontinence the bladder is distended and empties by over-

flowing. If residual urine is present, bladder neck resection may help. However in these cases renal function is easily disturbed and no method of treatment is satisfactory. Cystotomy must be performed if signs of kidney damage are present.

The most frequent urinary complications in paraplegics are cystitis and ascending and hematogenous pyelonephritis. They are often associated with bladder stones and are more frequent in bedridden patients. The G and M solutions may dissolve or reduce the volume of the calcium carbonate and calcium phosphate calculi. However the larger calculi must be removed surgically. Streptomycin may help when penicillin or the sulfonamides do not succeed but it rarely stops an infection if a bladder stone or a suprapubic fistula is present. The prognosis of urinary infections in paraplegics remains poor.

GEORGE PERRET, M.D.

PERIPHERAL NERVES

Tensile Strength of Human Nerves. An Experimental Physical and Histologic Study. C. T. LIOU, C. E. BENDA, AND F. H. LEWIS. *Arch. New Psychiat.*, Chic., 1948, 59, 332.

These authors have performed a very useful function in publishing the results of their obviously carefully made experiments on the tensile strength of human nerves. Their material consists of 32 human nerves—3 sciatic, 4 ulnar, 7 tibial and 8 peroneal—which were removed from cadavers 6 to 12 hours after death when death was in no way related to any condition of the nerves.

The authors are aware of other optimistic reports concerning the stretch capability of human nerves but they feel that the important question is not when complete rupture occurs but at what force damage to single nerve fibers first appears and thus they have demonstrated very well by means of a simple tensiometer. Their methods and statistics, neither of which are complicated, show that herniation of the nerve fibers through the sheath begins in the sciatic nerve at a 32 per cent stretch and in the peroneal nerve at 16 per cent. They demonstrated to their own satisfaction that the actual tension expressed in kilograms per square centimeter of the tested nerve is not so good a guide to nerve damage as the actual percentage of stretch produced. One of the ulnar nerve specimens stretched 47 per cent under a tension of 15.3 kgm. per square centimeter and in this specimen two of the three main fascicles composing the nerve were ruptured while the third fascicle showed minor damage at different levels. The endoneurium is apparently less elastic than the perineurium and often is torn transversely together with the nerve fiber bundles. The endoneurium was torn at about 20 per cent stretch. Microscopic hemorrhages were frequently noted about the endoneurial vessels. The nerve fibers in most cases were observed to be completely interrupted when the nerve was stretched beyond 10 per cent. The myelin sheaths were frequently fragmented.

Apparently the axis cylinder and myelin are the least resistant to stretch, whereas blood vessels endoneurium and perineurium are more resistant. The authors believe therefore that no human peripheral nerve should be stretched more than 6 per cent of its length beyond which point severe internal microscopic fracture occurs in various places. Under such conditions the degree of recovery will be greatly minimized. The significance of their findings is important in the repair of severe peripheral nerve lesions during which the effect of stretching may not be known to many surgeons. JOHN MARTIN, M.D.

Post Traumatic Ossification of the Peripheral Nerves. Histogenetic Study of Heterotopic Ossification of the Nerves (Ossification posttraumatique des nerfs périphériques). Studio sull'istogenesi delle neoformazioni ossee eterotopiche. LEONARDO GUT. *Chir. org. motum.*, 1948, 32, 241.

The author presents 7 cases in which calcification developed in and about the cicatricial regions of an injured nerve. Microscopic studies were made of the removed osseous neoformations. Three of these patients had suffered injury to the sciatic nerve (1 with and 2 without associated fracture), 1 patient had an injury of the median nerve, 2 patients had suffered injury to the radial nerves without associated fracture, and 1 patient had suffered an injury to the axillary nerve with associated fracture of the clavicle. The osseous processes were of no special significance as the nerve tissues themselves did not take part in the abnormal process of calcification and the newly formed bone was easily removed without any effect on the ultimate outcome of the case.

Microscopic study of the removed tissues demonstrated that the osseous tissues in each case were entirely independent of the neighboring bone apparently taking origin from the cicatricial changes between the ends of the injured nerve or from the tissues of the perineurium.

From his studies of the tissues in this group of cases the author is led to regard the theory of cellular new bone formation as postulated by Lenche and Polycard (wherein the lime salts are laid down directly within the meshes of the collagen fibers of the connective tissue without any participation on the part of the connective tissue cells themselves or cells derived from elsewhere in the body) as not adequately explaining all the findings observed in these cases. For the general process of osteogenesis the clarifications of S. Kromprecher (*Die Knochenbildung*, G. Fischer, Jena, 1937) are accepted as embodying the classical opinions on the subject. With this theory the process of ossification is mediated by special cells (reserve cells) which normally lie dormant among the connective tissue cells until roused to form osteoblasts by the stimulus of the injury or of some other unknown factor. However Kromprecher's clarifications are not accepted in full. It is the author's impression that these osteoblasts arise as a transmutation of young connective cells.

Neurogenic Bladder (Vejiga neurogenica) Hictor
VALLADARES A Arch. Soc. cir. hisp. Santiago, 1947
17: 383

The author reviews the anatomy and innervation of the urinary bladder and emphasizes the necessity of using cystometry for the correct diagnosis of functional disorders of the organ.

In the hypertonic bladder the sensitive cystometric points are displaced to the left, with a rapid increase of the manometric pressures. The so-called efferent neurogenic bladder of Simons is characterized by a small hypertonic bladder with great predominance of the parasympathetic function. It is encountered particularly in pyramidal lesions, multiple sclerosis, medullary tumors, and partial medullary involvements. The hypotonic bladder is characterized by displacement of the sensitive points to the right and by an organ of great capacity which is called afferent neurogenic bladder. Its mechanism seems to be determined especially by a considerable decrease in sensitivity which causes atony and atrophy of the detrusor muscle. This bladder has a very low pressure and empties poorly leaving a large residue. It is found in *tabes dorsalis* and in lesions of the cauda equina.

Every urologist has seen patients with traumatic lesions of the brain, cerebral tumors, hemorrhages or inflammatory processes who, while conscious had involuntary micturitions. These patients have vesical retention during the period of shock later they develop urinary symptoms connected with loss or decrease of function, they are incapable of starting micturition voluntarily or of controlling it.

In incomplete high medullary lesions the neurologic symptoms vary with the extent of the damage there may be delay in starting urination which then occurs with little force and a weak stream. In complete high lesions, as in traumatic cases or in myelitis, there is immediate retention, which may last for hours or days, followed by incontinence due to overflow and finally the establishment of a certain degree of urinary automatism. If the case becomes complicated by cystitis or any other kind

of acute infection the automatic mechanism is profoundly altered and the bladder becomes small, hypertonic, and with little capacity. Therefore, the treatment of vesical function must be in the hands of the specialist from the beginning.

In traumatic lesions of the lumbar and sacral segments the same stages are observed retention, incontinence from overflow and automatism. But the latter is hard to attain especially in lesions of the sacral regions in which so-called paralytic incontinence is the rule. It is obvious that if the reflex center itself is involved the degree of automatism obtained will depend on the degree of damage sustained. Therefore, in these cases aseptic measures are imperative to preserve a good bladder function from the beginning.

In lesions of the cauda equina, and especially those in which the nerves corresponding to sacral nerves 3 and 4 are destroyed extremely grave changes are produced because the principal routes of the vesical automatism are interrupted. Theoretically such a lesion should never improve but here occurs the best defense against traumatism because the displacement of the roots prevents their total destruction.

The lesions produced in *tabes dorsalis* consist basically of an interruption of the sensorial reflex arc in such a form that the muscular tonus has disappeared with the production of an exaggerated stretching of the bladder wall this results in an organ of large capacity with very low tonus and contraction that always leaves a large residue the urinary stream is thin with final dribbling which may continue for some time.

In bilateral chordotomy incontinence is frequent, but not as frequent as has been reported in unilateral chordotomy when a urinary complication occurs, it is a retention of short duration and the bladder function returns in a few days.

In hernias of the intervertebral disc in which it is necessary to displace the nerve roots beyond the midline, periods of postoperative retention are observed which may persist for some days but recovery of function is complete and practically normal.

RICHARD KENDER, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Advanced Mammary Cancer MAX CUTLER and
MELVIN SCHLEMMERSON *J. Am. M. Ass.* 1948 138
187

Twenty consecutive patients with advanced mammary cancer were treated with testosterone propionate intramuscularly. Initial doses of 300 mgm. were followed by 150 mgm. twice weekly until between 2,250 and 4,650 mgm. were given to the 5 patients whose cases are reported in detail.

Four of the 20 patients showed definite improvement in their condition. In 1 patient there was skeletal metastasis; in another skeletal and soft tissue metastasis; and in 2 patients soft tissue metastasis. Recurrence developed in all of them within a year. The longest period of improvement was 11 months. Four patients, all with the disease confined to the soft tissues, showed transitory improvement in their condition with temporary tumor regression and improvement in their well being. Twelve patients showed no significant improvement. 6 of these had only soft tissue involvement and 6 only skeletal involvement initially, although 3 developed skeletal metastases while under treatment. There was no evidence that the disease was accelerated by the treatment in any of these 12 cases.

On the experience with these 20 cases it seems advisable to withhold testosterone therapy until other well established procedures have reached the limits of their usefulness. Both surgical castration and roentgen sterilization frequently produce results which are comparable to those seen following testosterone therapy. Because testosterone increases the retention of sodium, potassium and protein nitrogen and hence water, testosterone should be used cautiously in patients with cardiac disease. It is suggested that treatment, when favorable, be continued until the palliative effect is no longer evident because in the present cases when treatment was stopped a second course of testosterone did not renew the initial favorable effect.

Masculinization and cessation of the menses occur when more than about 200 mgm. of testosterone are administered per month. There is no evidence that cure can be achieved by testosterone therapy and palliative results can be anticipated in only a relatively small number of patients.

TRACHEA, LUNGS, AND PLEURA

Exploratory Thoracotomy in the Management of Intrathoracic Disease. JOHN B. GROW, MARTIN L. BRADFORD and HUGH W. MAHON *J. Thorac. Surg.*, 1948 17 480.

The present day use of mass x-ray surveys of the chest and the taking of chest roentgenograms rou-

tinely on hospital admissions in many institutions has disclosed an increased number of asymptomatic thoracic lesions. Consecutive hospital admission roentgenograms are estimated to present evidence of thoracic disease in from 8 to 10 per cent of cases.

Such cases tax the clinician's diagnostic ability severely because all too frequently a conclusive diagnosis cannot be made even after the most complete and exhaustive study. As a final diagnostic approach in such cases exploration is recommended.

The authors report on an experience with 200 consecutive exploratory thoracotomies performed at Fitzsimmons General Hospital, Denver, Colorado between September 1942 and April 1947.

The lesions were distributed in the following locations: the mediastinum 73, the lung, 113, outside of the lung (exclusive of mediastinal and vascular) 8 and in the heart and great vessels 6.

In these cases there was an overall incidence of malignant lesions of 21.5 per cent. The roentgen appearance of the pulmonary conditions was that of circumscribed lesions in 86 cases and of atelectasis in 35 cases. The circumscribed lesion was proved to be malignant in 21 cases and tuberculous in 37. The atelectasis resulted from bronchogenic carcinoma 11 times and from tuberculosis 3 times. Sixteen per cent of the mediastinal lesions were proved to be malignant.

The various possible diagnostic procedures are given brief appraisal. It being pointed out that positive bronchoscopic biopsy can be expected in only about 50 per cent of the resectable neoplasms. Likewise the practice of relying on a test dose of x-radiation as a means of identifying members of the lymphoblastoma group of tumors is condemned because

1. All malignant lymphomas do not respond to x-ray therapy.

2. Many benign lymphadenopathies and resectable malignant lesions of the thymus do respond to irradiation and this would lead to an erroneous diagnosis.

3. There are indications that the prognosis of localized mediastinal lymphoma is improved by combined resection and irradiation therapy.

4. The prompt establishment of a histologic diagnosis expedites the initiation of treatment.

Since the incidence of malignancy is significantly high in the obscure intrathoracic lesions described and the treatment of choice in the vast majority of nonmalignant conditions is surgical removal anyway, exploratory thoracotomy is recommended after the more conservative diagnostic methods which are employed expeditiously have failed to clarify the condition.

The risk of exploratory thoracotomy per se is nil, the mortality being dependent upon the gravity of the therapeutic portion of the operation. There

were 8 deaths in the series 5 following pneumonectomy for cancer and 3 death following pneumonectomy for blastomycotic suppurative disease; 1 death followed a lobectomy and the last death occurred in a patient with an inoperable neurogenic sarcoma. The morbidity was as follows 12 pleural effusions 5 postoperative atelectasis 3 minor wound infections and 4 empyemas.

HIRSH T. LANGSTON, M.D.

Transstracheal Anesthesia for Bronchoscopy DWIGHT E. HARRIS and ARNOLD M. SALSBURG. *N. England J. M.* 948, 290-293.

Since bronchoscopy contributes greatly to the diagnosis and treatment of intrathoracic disease the use of a proper anesthetic during the operation serves the interest of both the patient and the bronchoscopist.

A method of administering a dilute pontocaine solution for bronchoscopic anesthesia via the cricothyroid membrane directly into the trachea is described. The technical details of the procedure are outlined.

The safety of the method is supported by experience in more than 1,000 patients. Only 3 of the patients developed a superficial cellulitis of the soft tissues about the site of the injection. This method of anesthesia should not be used in the presence of extensive tuberculous disease of the larynx and upper trachea since there may be danger of the development of a tuberculous sinus in such cases. No sinuses, however, resulted among the 1,000 cases described, though the anesthesia has been extensively used in open cases of tuberculosis.

The application of this form of anesthesia in bronchoscopy for the removal of foreign bodies is contingent upon the position of the foreign body itself.

SAMUEL KARY, M.D.

Chronic Nonspecific Suppurative Pneumonitis. RICHARD D. KETTERER and W. E. ADAMS. *J. Thorac. Surg.* 948, 7-9.

This article describes the clinical picture of a pulmonary condition which is sufficiently well defined to be considered a disease entity. The report is based on an experience with 10 cases of suppurative pneumonitis.

The disease is characterized by an insidious onset, chronic course, productive cough and hemoptysis and a diffuse chronic inflammation of the lung without abscess formation.

The clinical characteristics include chest pain with low-grade fever as well as cough and hemoptysis. The symptoms have lasted from 6 months to as long as 22 years. Females predominate 5 to 1 among the patients so afflicted and the 30 to 50 age group is chiefly affected.

The condition must be differentiated from bronchogenic carcinoma, chronic lung abscess, tuberculosis, and bronchiectasis. The principal features

of the differential diagnosis are the gradual onset of symptoms without obvious cause and diffuse infiltration of the lung without signs of bronchial dilatation or cavity formation on x-ray examination. Differentiation from bronchogenic carcinoma in the cases of short duration usually must await pathologic study. No definite etiologic agent has been found. The bacteriologic flora is nonspecific. Tubercle bacilli are of course absent.

The basal portions of the lung were involved more frequently than the upper, the right side more often than the left, although 1 case was bilateral. The pathologic picture includes interstitial fibrosis, thickening and fibrosis of the alveolar walls, lymphoid hyperplasia, narrowing of the bronchial lumen by redundant mucosa, chronic atelectasis, and infiltration by macrophages.

The treatment recommended is resection. Under medical management many of the patients showed transient improvement, but the symptoms recurred and progression of the lesion could be demonstrated with x-rays. Most of the patients became significantly incapacitated.

Surgery with drainage or resection was employed in 9 patients. In 1 case only was a biopsy taken (bilateral involvement). The 9 patients all returned to full activity in 1 to 3 years except 1 who died of pneumonia 5 days after operation. Resection is preferred because the period of morbidity is shorter than with drainage (with resection the hospital stay averaged 22 days as against 50 days with drainage and clearing of the lung fields occurred in from 6 to 7 months as against 12 months) and the relief of symptoms is likely to be more complete. Also when bronchogenic carcinoma cannot be ruled out, an added reason for resection is present.

The text is supplemented by illustrative roentgenograms and photographs. Statistical data is presented in tabular form. Two detailed case histories are appended.
HIRSH T. LANGSTON, M.D.

Pulmonary Decortication in the Treatment of Early Pyogenic Empyema. EDWARD F. PARKER and THOMAS H. DUFFORD. *Surgery* 3648, 2423-2424.

The authors have revived the idea of early post-empyema mobilization of the lung. They state that in order for decortication to be successful three conditions must prevail and for the most part they are present before the empyema is "chronic": (1) there must be a line of cleavage between the inflammatory membrane and the capsule; (2) the underlying viscera must be normal rather than thickened and fibrotic (this tends to be the case early in the course of the empyema); and (3) the lung must be intact and able to expand completely, not atelectatic.

Indications for primary decortication without preliminary drainage are: (1) the presence of a massive cavity causing 50 per cent or more collapse of the lung and more particularly if collapse involves the apex of the lung; and (2) fever of no more than from 102.0 to 103.0 degrees as this does not

contraindicate primary operation if the patient does not appear too toxic. The time for primary decortication from a pathologic standpoint is within 6 weeks of the onset of empyema and preferably as soon as the diagnosis is made and the patient is prepared.

Secondary decortication is indicated for the same reasons as already stated and is done in early empyema—that is, 4 weeks after adequate rib resection drainage. If the lung fails to expand further and the empyema cavity does not diminish a secondary decortication is done. Needless to say, if there is present a lung abscess or a bronchopleural fistula it must be eradicated at or before the time of decortication.

The two important factors in successful post-operative management are (1) complete pulmonary expansion maintained by drainage and (2) parental and local antibiotic therapy for from 7 to 14 days postoperatively.

Two cases of primary decortication done 33 and 41 days after onset of empyema, respectively are reported. Three cases of secondary decortication done 31, 38 and 32 days respectively after rib resection are presented.

JANE C. MACMILLAN M.D.

Studies in Lung Abscess. The Etiology of Lung Abscess. R. C. BROCK. *Guy's Hosp Rep Lond* 1948, 96: 141.

When sufficient care is taken in elucidating the history of lung abscess a primary or existing cause can be found in about 75 per cent of the cases. Only after all avenues of approach are exhausted should the diagnosis of primary lung abscess be accepted.

Many analyses of the etiology of lung abscess have been made in the literature. Among the causes listed are operations on the upper respiratory tract, such as tonsillectomy, tooth extraction and sinus operations; other operations under general anesthesia; pneumonia; influenza; malignant disease; bronchiectasis; acute respiratory infections; dental sepsis; and such causes as epilepsy, alcoholic stupor and submerision. The percentages of these causes have varied greatly from one series to another. It is also of interest that in some large series no mention is made of malignant disease and it is quite striking that dental sepsis as a cause is omitted in most series.

In a series of 363 cases of lung abscess composed of one group of 276 consecutive cases seen from 1942 through 1946 and a second group of 87 operative cases the basic etiology is analyzed. Forty-seven cases (13%) were due to bronchial carcinoma. Other nonmalignant causes which were identified involved 223 cases (61.5%) making a total of 270 (74.5%) in which the causes were identified. Thus only in 93 cases (25.5%) was the cause obscure and the diagnosis of "primary lung abscess" made. Of the 316 non-malignant cases 80 (25.5%) were found to be post-operative, 41 occurring after abdominal operations and 39 after nonabdominal operations. Of the latter 25 occurred after tooth extraction and 7 after tonsil-

lectomy. Sixty cases (19%) were classed as being due to dental sepsis. Specific infections with the Staphylococcus, Streptococcus, Friedlander's bacillus, and the Actinomyces accounted for 16 cases (8%). Fifty-six (18%) resulted from various identified causes making a total of 222 cases (70%) in which the causes were identified. Ninety-four cases (30%) were classed as obscure primary or cryptic lung abscesses.

The various factors responsible for the high incidence of lung abscess following tooth extraction appear to be multiple extractions under deep anesthesia, extraction of septic teeth with tartar masses, upright position in the dental chair and badly given nitrous oxide anesthesia with cyanosis and obstructed respiration. The position of the patient during recovery from anesthesia for operation on the mouth, nose and pharynx is an important consideration, the prone position provides the greatest freedom from the risk of bronchial embolism, as fewer bronchi are vulnerable in this position. Raising the patient's feet lessens the risk even more.

Gross dental sepsis is a very important factor in the etiology of lung abscess and elective surgery should not be embarked upon in the presence of pus pockets, gum infections, and tartar masses. Anesthetists and surgeons alike share the responsibility for proper preoperative dental care in all but emergency cases.

In patients below the age of 15 the cause of lung abscess is almost always identified, the most common cause being staphylococcal pneumonitis. Contrary to the usual belief abscess secondary to an inhaled foreign body is quite rare, only 3 cases being encountered in the entire series.

In young adults from 15 to 25 years of age the cause is usually apparent. An operation is the most likely preceding event, tooth extraction and tonsillectomy being of equal importance.

In older patients the proportion of cases in which the cause cannot be identified or is found only after searching inquiry increases. Preceding operation including tooth extraction and gross dental sepsis are leading causes. Carcinoma must be considered in this group. In obscure cases such items as the patient's occupation, alcoholic intoxication, epilepsy, immersion and overdose of sedatives must be thought of and asked about specifically. Tuberculosis always demands exclusion, especially in obscure middle lobe abscesses. With increased knowledge, experience and diligence the percentage of "obscure" or primary lung abscesses should continue to decrease.

JESSE E. THOMPSON M.D.

Nonmalignant Intrathoracic Lesions Simulating Bronchogenic Carcinoma. LYMAN A. BREWER, III, WILFRED M. G. JONES, and FRANK S. DOLLEY. *J Thorac Surg*, 1948, 17: 439.

In the authors' experiences with 300 cases of lung carcinoma only about one-half could be visualized by bronchoscopy. The authors have classed those lesions of the lung beyond the limits of bronchoscopic

diagnosis as peripheral, and in this presentation they review 30 nonmalignant intrathoracic conditions which simulated bronchogenic carcinoma and which were subjected to surgery. The 30 were as follows:

Inflammatory	20
Lung abscess.	6
Tuberculosis	5
Pneumonia	5
Bronchiectasis	3
Granuloma	
Echinococcus	
Silicosis	
Benign tumors	6
Adenoma.	3
Lipoma	
Fibroma	
Developmental	4
Cysts	3
Thyroid	

Of these 30 benign instances 23 could not be expected to end in recovery with conservative treatment, 6 cases were equivocal, and 1 case was hopeless regardless of the type of treatment employed. Twenty-seven patients were cured by surgery, 2 were not benefited, and 1 patient died after operation.

The authors emphasize the difficulty in establishing the preoperative diagnosis of bronchogenic carcinoma in locations where visualization and biopsy by bronchoscopy is not possible and conclude with a recommendation for exploratory thoracotomy when carcinoma cannot definitely be eliminated. If carcinoma is found, pneumonectomy is the procedure of choice. If a benign lesion is present, this series indicates that in most instances simple local resection is necessary.

The authors liken the management of suspected bronchogenic carcinoma to that of suspected mammary carcinoma, in which exploration and biopsy are done followed by radical excision if cancer is found.

C. FREDERICK KITTLE, M.D.

The Diagnosis and Operability of Bronchogenic Carcinoma. JOHN H. GIBSON, JR., LOUIS H. CLEGG, PETER A. HENRY, and JOHN J. DETMERS. *J. Thorac. Surg.* 1948, 17, 49.

Carcinoma of the lung ranked fourth as the cause of death among cancer mortalities in 1944. Because of this, the need for its earlier diagnosis, more radical operation, and the reduction of postoperative mortality are stressed by the authors in consideration of 56 consecutive cases of bronchogenic carcinoma seen at Jefferson Hospital, Philadelphia.

Education of the public and the general practitioner in the recognition of premonitory symptoms will help most. The first symptoms in this series in order of decreasing frequency were cough, production of sputum, chest pain, hemoptysis, weight loss, dyspnea, wheezing respiration and bouts of poor

months. A diagnosis of virus pneumonia or unresolved pneumonia in males between the ages of 40 and 70 years should not be made without excluding the possibility of a carcinoma, which occludes the bronchus with infection distal to the point of obstruction. Roentgenoscopic examinations in patients with bronchogenic carcinoma almost always reveal some abnormality. Bronchoscopy will often confirm the diagnosis suggested by the x-rays, provide a positive biopsy or in rare instances disclose a tumor not apparent on roentgenological examination. Needle biopsy may be done in those instances in which the tumor is peripherally located, but this method is not particularly recommended. An important adjunct to the diagnosis of bronchogenic carcinoma is the cytologic study of bronchoscopic aspirations. If no secretion is obtainable from the bronchus, from 2 to 3 c.c. of salt solution may be injected into the bronchus and then removed. Of 118 cases studied by this method by the authors 90 per cent showed neoplastic cells, while in the same group only 45 per cent provided a positive bronchoscopic biopsy. In some patients a definitive diagnosis can not be made without exploratory thoracotomy.

All patients should be subjected to thoracotomy unless there is unequivocal evidence of extension of the disease beyond the hemithorax in which the tumor lies or unless a pleural effusion exists which is bloody or contains malignant cells. In the group with nerve palsies indicating involvement of the phrenic nerve, recurrent laryngeal nerve, or sympathetic trunk, the issue is debatable, some tumors being resectable by block dissection and others being inoperable.

The decision as to whether or not a pneumonectomy should be done is based on the same principles as are applied to cancer surgery for tumors located elsewhere in the body. If all visible and palpable tumor can be removed without leaving any evidence of malignant tissue the authors believe a radical pneumonectomy should be done. The procedure suggested by Allison is believed most effective; this consists of intrapericardial ligation of the pulmonary vessels at their junction with the left auricle.

In 20 pneumonectomies and one partial removal of the right lower lobe by the authors there were 2 deaths, one due to tension pneumothorax, the other from an empyema secondary to bronchopleural fistula. This represents a considerable decline in postoperative mortality from previous years.

C. FREDERICK KITTLE, M.D.

The Treatment of Inoperable Bronchogenic Carcinoma with Methyl-Bis. EDWARD F. SCHROEDER, DUANE CARR, and WILLIAM E. DEEMAN. *J. Thorac. Surg.* 1948, 17, 428.

The authors report their experiences in the treatment of 25 patients with inoperable bronchogenic carcinoma by means of methyl bis (beta-chloro-ethyl amine hydrochloride), a derivative of the nitrogen mustard compounds best known for its palliative action in lymphomas. Methyl-bis has been shown to

produce its effects by direct action on the chromosomes

Their procedure consisted of the intravenous administration of 0.1 mgm. of methyl bis per kilogram once daily for 4 days usually with 1,000 c.c. of isotonic saline solution. This was repeated in 2 or 3 months and more often when desired the patient usually being hospitalized for 5 days during the administration of methyl bis. The history physical status blood count and fluoroscopic or x ray findings were ascertained every 2 weeks.

About 50 per cent of the patients develop varying degrees of nausea vomiting and anorexia after administration of this chemical but these conditions are usually of shorter duration than when they are caused by x ray treatment. This incidence can be reduced by giving 100 mgm. of pyridoxine hydrochloride early in the morning of the treatment day. From 10 to 20 per cent of the patients may require blood transfusions to combat the erythrotoxic effect of methyl bis.

Methyl-bis is more advantageous than x ray therapy because it is cheaper is more easily administered may be used in cases with widespread metastases in which irradiation is of little value and because the toxic symptoms are less severe.

Twenty five patients with far advanced bronchogenic carcinoma were treated with methyl-bis. Of these 3 had adenocarcinoma, 5 had squamous-cell carcinoma and 17 had undifferentiated cell carcinoma. The clinical course of 17 is reported in detail and of these 10 received irradiation in combination with the methyl bis. The majority of the patients showed improvement in their condition as manifested by weight gain decrease in cough dyspnea and bouts of pulmonary infection and by the alleviation of pain.

This chemical is suggested as a palliative agent in the treatment of inoperable bronchogenic carcinoma.

C. FREDERICK KITTLE, M.D.

ESOPHAGUS AND MEDIASTINUM

The Importance, and a Discussion of Connectivomas of the Upper Respiratory Tract (Relievi e considerazioni sopra i connettivomi delle alte vie aeree) CARLO SIRTORI and CESARE BECCHERLE. *Tumori Milano* 1948 34: 12

During a period of 20 years the authors treated 175 patients with connective tissue tumors of the upper respiratory tract. There were 77 reticulosarcomas 37 angiosarcomas and fibrosarcomas 31 sarcomas 7 lymphosarcomas 6 epulis 5 osteomas 4 endotheliomas 3 fibromas 2 chondromas 2 plasmacytomas, and 1 lymphoepithelioma.

Reticular cells even if they become malignant, preserve their evolutionary omnipotence. According

to the predominating tendency sarcomatous histiocytic, and endothelial varieties of reticulosarcomas may be distinguished. Occasionally an evolution of the same group of tumors toward fibrosarcomas or lymphosarcomas may be observed. Aplastic forms or reticulosarcomas in the strict sense of the word must be distinguished from blastic forms such as histiocytic fibrocystic, endothelial or lymphocytic types. A precise diagnosis is of importance for the prognosis: pure reticulosarcomas and the lymphosarcomatous forms are more malignant but also more radiosensitive than other types.

Polyps may assume the form of a circumscribed elephantiasis with all the evolutionary possibilities of such formations.

Typical and atypical forms of blastic sarcomas may be distinguished: Myxoblastic, fibroblastic, lipoblastic, angioblastic, chondroblastic, and osteoblastic tumors belong to this group. The anaplastic sarcomas may also be divided into typical and atypical types. Such classification is of clinical importance. Typical blastic sarcomas are relatively benign. They easily recur and infiltrate adjoining tissues but they rarely produce distant metastases. Atypical blastic tumors show a greater aggressive infiltrating activity and form distant metastases. Atypical anaplastic sarcomas possess the highest degree of malignancy.

MISCELLANEOUS

Radical Extirpation and Primary Closure of Deep Thoracic Fistulas. JENY L. HANSEN. *Acta chirurgica*, 1948 96: 485

A method for the operative treatment of deep thoracic fistulas with chronic empyema or abscess of the lung is described. A regular large thoracotomy is made and all pathological tissue is removed. The extirpation extends from the skin fistula to the inner side of the thoracic wall and on or in the lung where the bronchial fistulas are sutured. The wound cavity is powdered with penicillin and sulfathiazole. Primary suture is done in layers with silk. The wound exudate is aspirated daily and systemic treatment with penicillin and sulfathiazole is administered.

Five case reports are presented. In 1 patient a drain had to be used on account of persistent infection. In this case the organisms were resistant to penicillin and sulfathiazole. In all other cases primary healing was achieved. In less than a month all of the patients were cured of an illness lasting from 6 to 12 months.

The operation causes no deformity of the skeleton gives the best possible lung function and requires only simple postoperative treatment.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

The Hernia Problem, with Reference to a Modification of the McVay Technique. JACK M. FARRIS, JEROME EITZINGER, and JOSEPH A. WEINBERG. *Surg.* 1948, 24, 793.

The authors contend that indirect hernias, particularly in young people are best dealt with by simple excision and transfixion of the hernial sac with minimal disturbance to either the cord or the floor of the inguinal canal. Suturing the conjoint tendon to Poupart's ligament is fallacious because (1) there is no weakness in the floor of the canal, (2) nowhere in human anatomy is muscle used as a buffer state and (3) muscle fixation is bound to result in atrophy from disuse. About 75 per cent of recurrences do not occur through the posterior wall but through the internal ring; therefore operations designed to reinforce the floor of the canal are ill conceived.

Simple ligation of the sac is inadequate if the internal ring is dilated or if there is weakness of the posterior wall of the inguinal canal. When the latter exists the problem is the same as in direct hernia.

The authors summarize the anatomical studies of McVay and Anson which note that the transversalis fascia, transversus abdominis and internal oblique muscles do not insert on the inguinal ligament, and that suturing of these structures to the inguinal ligament violates the surgical principles of restoring musculofascial anatomy to normal.

Cooper's ligament herniorrhaphy is the operation of choice in dealing with large indirect hernias (with associated defect of the inguinal floor) direct hernias, recurrent hernias and femoral hernias. The authors describe the surgical technique employed and supplement the article with four excellent illustrations.

ELY ELLIOTT LAZARUS, M.D.

The Relation of Incisional and Inguinal Hernias, as Well as of Mechanical Intestinal Disturbances, to Previous Operations for Appendicitis with Peritonitis. ALVIN PIRROLD. *Acta chir. scand.* 1948, 96 Suppl. 38.

The author presents a survey of clinical material on the subject of incisional and inguinal hernias studied from many different points of view as well as his personal observations on many aspects of the subject. Considerable space is given to an historical account of the development of therapy in these cases. The clinical material was obtained from three different hospitals.

The author was unable to establish any relationship between age and the occurrence of inguinal hernia; however he noted that incisional hernias occurred more frequently in women than in men. He also noted that incisional hernias occurred somewhat more frequently in intellectual workers than in laborers. He noted an increased predisposition to

incisional hernia in cases in which the time between the onset of the disease and operation was prolonged. The incidence of incisional hernias increased as the stage of the disease advanced which finding is compared with appendicitis with perforation and appendicitis without complications. A prolonged period of drainage also predisposes to incisional hernia.

The author observed that inguinal hernia occurred more frequently following use of the McBurney incision than with Lennander's and Krogh's incisions. Total intestinal occlusion occurred more frequently after operations for conditions in the "abacoma stage" than in conditions operated upon earlier.

GASTROINTESTINAL TRACT

Diagnostic and Therapeutic Problems in Diverticulitis. C. P. LILLY, JR., and BENJAMIN V. WHITE. *Y. Eng. J. M.* 1948, 30, 243.

During the 30 year period from 1917 to 1946, 300 cases of diverticulitis were seen at the Hartford Hospital, Hartford, Connecticut, which serve as the basis for this study. Of these 50 were complicated by perforation or obstruction. This incidence as noted by the authors, is much higher than in the community at large as many patients are selected for hospital admission because of symptoms attributable to the complications rather than to the disease itself.

Diverticulosis and diverticulitis are relatively common in persons past the age of 45 years. Diverticulitis occurs at some time in from 17 to 27 per cent of all cases of diverticulosis. The authors of this article emphasize the difficulties of diagnosis that arise from confusion with diseases affecting neighboring organs rather than the incidence statistics, and pathological features of the disease.

In the 300 cases of diverticulitis reported, the diagnosis was made by means of the clinical picture in addition to the x ray findings in 161 cases, at operation in 33 cases, by the clinical picture alone in 5 cases, and at autopsy in 2 cases. Of the 32 patients in whom the diagnosis was made at operation, 15 were suspected primarily of having acute appendicitis, and 17 were operated upon with such pre-operative diagnoses as pelvic inflammatory disease, acute cholecystitis, intestinal obstruction, and ruptured ovarian cyst. However in none of these 32 cases was a barium enema given.

The leading signs and symptoms were similar to those described by others and consisted of abdominal pain, fever, constipation, leucocytosis, diarrhea, back pain, and melena.

The authors noted pain in the lower back in 50.5 per cent of their cases. Heretofore little emphasis had been placed on this symptom, but in their experience this symptom may be a striking part of the

clinical picture. Another symptom often the presenting complaint, was the passage of blood by rectum. This may appear as free blood or as flecks on the fecal material. Melena occurred in 16.5 per cent of the cases reported in this series. This sign is somewhat disconcerting, because it detracts from the significance of blood in the rectosigmoid as an indication of polyps or other neoplastic lesions and complicates the differential diagnosis.

Of the 200 Hartford Hospital patients 161 had barium enemas that showed diverticulosis in the colon and 133 of these demonstrated definite spasm of the sigmoid with narrowing of the lumen. A mass was demonstrated by barium enema in 33 of the 161 and the mass was invariably in the sigmoid region. However the appearance of a mass on x ray examination is not necessarily diagnostic, since it may indicate an unrelated carcinoma or other disease.

Complications were encountered in 50 cases or 25 per cent of the series. There were 43 cases of perforation and 7 cases of mechanical obstruction due to local inflammation. Of the cases of perforation, 32 led to local abscesses 1 to generalized peritonitis 4 to mechanical ileus and 6 to fistulas.

Sixty three operations were carried out, 19 for diagnostic purposes. In all of the patients there was acute diverticulitis of the sigmoid. Six patients were operated on for other conditions and acute diverticulitis was found incidentally. There were 38 therapeutic surgical procedures which included irrigation and drainage of abscesses, colostomy, cecostomy, Mikulicz procedures and resections.

EDWARD F. LEWISON, M.D.

Diverticula of the Stomach. Report of 26 New Cases.

S. P. BRALOW and M. A. SPELLBERG. *Gastroenterology* 1948, 11, 59.

The authors discuss the available literature and report 26 new cases of apparently true and 4 cases of false or acquired gastric diverticula. This number represents about 0.015 per cent of all admissions but 2.6 per cent of 350 gastroscopies showed gastric diverticula. Apparently the incidence of this lesion is not as rare as is generally believed.

Radiologically their series showed 17 true diverticula located on the posterior wall of the lesser curvature of the cardia while 7 were found at the same location in the pars media. Two were observed on the greater curvature of the cardia. Of the false or acquired diverticula, 3 were found in the pyloric region on the lesser curvature and 1 was observed at the posterior wall of the greater curvature in the pars media. Two of the 3 pyloric diverticula were on the posterior wall and the third was on the anterior wall.

All 26 of the authors' patients had symptoms referable to the gastrointestinal tract at one time or another but 15 had associated lesions that probably contributed to the symptomatology. In general, however, the symptoms are neither diagnostic nor characteristic, but may be incapacitating with pain, vomiting and hemorrhage. It is probable that the

production of symptoms depends upon complications such as inflammation or ulceration of the diverticulum and that both of these may depend on retention of food particles in the sac. Occasionally a gastric diverticulum may cause typical ulcer pain which is relieved by food and alkalis.

The radiologic diagnosis depends on the retention of opaque media, and is most commonly seen after the stomach empties.

In the experience of Bralow and Spellberg gastroscopy for visualization of diverticula affords no more risk than gastroscopy for other lesions. The gastroscopic appearance is quite characteristic and cannot be easily confused with other lesions. The ostium of the diverticulum may be perfectly round or oval and may change in size and shape during observation. In some cases one may observe a ridge or slight elevation suggestive of a ring of muscle fibers surrounding the opening in other instances rugal folds resembling those seen in a gastric ulcer are observed radiating toward the ostium. The depth of the opening is dark, while in an ulcer crater the base is covered by an exudate.

As a rule the diagnosis of gastric diverticula is not difficult provided the clinician is mindful of this lesion and institutes careful roentgenographic and gastroscopic studies. It should also be kept in mind that since gastric diverticula frequently may be asymptomatic, their mere presence should not be accepted as the sole factor accounting for the patient's symptoms. Before attempting therapy it is imperative to make certain that the diverticulum is inflamed, retentive and the sole cause of the existing symptoms. If the symptoms are mild a medical regimen of a bland smooth diet, and alkalis and bismuth taken 1 to 2 hours after meals will afford relief. Gastric lavage and postural drainage may be helpful when retention in the diverticulum is present. Prolonged postural drainage is particularly advised for diverticula located at the cardia. However if the symptoms persist, or associated lesions such as benign or malignant ulcerations are suspected or found surgery is indicated. Total excision of the diverticulum with inversion of the stump should be attempted. Simple invagination of the pouch with a closure of the mural muscular ring by a purse string type of suture is not adequate.

During surgical exploration it is frequently difficult to find the diverticula. In 3 of the authors' 5 cases the diverticula could not be located at operation. To obtain the best exposure the gastroduodenal ligament and the gastroduodenal omentum may have to be divided. This maneuver will permit the mobilization of the fundal end downward and toward the midline. Occasionally the gastrophatic omentum also must be divided.

ROBERT TURNER, M.D.

Neurohumoral Aspects of Peptic Ulcer Formation

J. WEXNER and H. E. HERR. *Canad. Med. Ass. J.* 1948, 59, 115.

In spite of the early and many brilliant observations of clinical pathologists pointing to the asso-

ciation of brain damage and changes in the stomach the concept of the neurogenic basis for ulcer formation was given little consideration because of the dominating views of Virchow who held that peptic ulcer was essentially a local disease. Interest in this aspect of ulcer formation was revived by Cushing's Balfour Lecture. The authors, in an exhaustive and thorough review of the clinical and experimental evidence of the neurohumoral aspects of ulcer discuss the etiologic factors of chronic peptic ulcer in man.

In surveying the clinicopathological literature for evidence of the association of gastric and duodenal lesions with intracranial disorders the authors found that nearly all of the lesions were of the acute type. There was no special preference for localization and the gastrointestinal lesions were usually multiple. Almost all ulcers were a hemorrhagic type of erosion with edema of the mucous membrane. Most of the cases of gastrointestinal bleeding or perforation were noted very shortly after brain injury. Intracranial damage in the neighborhood of the third and fourth ventricle was most frequent in the cases of trauma.

Reviewing the experimental evidence, the authors believe that it may not be justifiable to interpret the types of responses obtained from hypothalamic lesions as purely sympathetic or parasympathetic, for evidently both systems were frequently activated simultaneously. It seems more correct to consider that lesions placed in the hypothalamus upset the autonomic regulating mechanism, thereby setting up a state of autonomic imbalance resulting in vasomotor changes in the gut. These may be severe enough to cause mucosal hemorrhage or acute ulceration. Although there is clear-cut evidence that hypothalamic lesions and lesions of the pons, medulla, and upper spinal cord may initiate acute gastrointestinal lesions, there is no evidence that these lesions have ever gone on to form chronic ulcers of the type seen in man.

Studies on vagotomies and splanchnicectomies confirm the work done on damaging the hypothalamus in experimental animals. By creating an imbalance in the autonomic innervation of the gut, there resulted alterations in gastrointestinal motility, secretion, and vascular changes in the mucosa. Acute ulceration may occur but rarely if ever do these changes go on to chronic ulcer.

Reviewing the relation of gastric secretion to peptic ulcer the authors conclude that the main body of evidence indicates that the nocturnal gastric secretion in patients with ulcer is generally greater in volume and higher in acidity than that found in normal subjects. However a more careful study under rigidly controlled conditions would be necessary before any definite conclusions could be drawn. The range of acidity of the gastric contents of patients with ulcer closely parallels that found in normal subjects varying from complete acidity to hyperacidity. The experimental evidence reviewed by the authors fails to offer convincing proof that hyper-

secretion of acid or excessive nocturnal gastric secretion are prime factors in ulcer pathogenesis. Acid peptic secretions only act upon mucosa which has already been injured.

The experimental and clinical evidence reviewed indicates that the absence or deficiency of intestinal secretions and mucus are not responsible for the production of ulcer per se yet the deficit of these neutralizing factors may be of some importance in ulcer formation. The work of Winkelshtein, Fogelson, Dragstedt, and Wangensteen is carefully considered.

Although the authors point out that vagotomy has yielded immediate relief of ulcer symptoms and has allowed for prompt ulcer healing the postoperative period of observation has been short. Wolf and Andrus have shown that gastric hyperemia and engorgement of the stomach mucosa due to vascular congestion induced by feelings of anger and resentment in a patient with a gastrostomy fail to occur after vagotomy. Thus, any permanent benefits from vagotomy may be the result of interruption of the cephalic impulses.

The work of many investigators is critically reviewed regarding the administration of pilocarpine, adrenalin, acetylcholine, mecholyl, histamine, pitressin and caffeine. The gastrointestinal lesions thus produced were all of the acute type.

Repeated vascular insults to the gastrointestinal mucosa produced by various experimental methods although severe enough, produced only transitory ulcers.

The authors in a review of more than 350 references conclude that there is a physiological basis for the neurogenic concept of ulcer formation. Marked circulatory disturbances initiate acute gastrointestinal lesions. The psychosomatic concept of ulcer formation is considered an important factor. Peptic ulcers may well be a pathological sequel to autonomic nervous imbalance created during sustained emotional strain or conflict.

EDWARD F. LEWISON, M.D.

Synthetic Resin—A New Antacid for the Treatment of Peptic Ulcer. MAXFRED KRAMER and LEO H. SIEGEL. *Arch. Surg.* 948, 56 3 S.

The discovery by Adams and Holmes, in 1935 that phenolic resins have ion exchange properties started a revolution in the chemical world. It now became possible to remove both acids and alkalis from solutions without changing the nature of the original solvent. Since these substances are nontoxic for human beings, it was inevitable that they would find a place in medicine.

The authors studied a synthetic resin, amberlite IR IV (metaphylene diamine) and believe that it approaches the ideal antacid in that it appears to be as effective as the usually employed salts of calcium, magnesium, and aluminum, but does not produce any of their untoward reactions. It is not absorbed from the digestive tract, has no effect on the acid-base balance and does not alkalinize the urine. It does not affect the bowels or irritate the gastric

mucosa. It neutralizes acid rapidly and promptly relieves pain. It is effective in small doses and is inexpensive and tasteless.

In the 60 cases studied it was used in doses ranging from 2 to 9 gm daily for from 6 to 8 months at a time with no evidence of toxicity as manifested by examination of the skin blood and urine. Considering freedom from pain as evidence of the healing of an ulcer 47 of the patients have been benefited by resin therapy. Six patients did not respond well to resin or to any other antacid therapy and required subtotal gastric resection. Three patients did not respond to resin therapy but did well when given other antacids. Two patients were not relieved by resin or other antacids but were kept free of symptoms by nightly aspiration of the gastric contents. Two patients could not be followed up adequately.

JOHN J. CRANLEY, JR., M.D.

Penicillin in the Postoperative Treatment of Peptic Ulcer with Perforation, and Appendicitis with Perforation ROBERT B. BROWN AND DON L. ANDRUS. *Ann. Surg.*, 1948 128 57

The present report is based on a study of 42 cases of perforated peptic ulcers and 97 cases of perforated appendices. These patients were operated upon at the Philadelphia Naval Hospital during the 18 month period between January 1, 1946 and June 30, 1947. Since the vast majority of these cases were surgical emergencies operation was performed by the surgical watch officer. All patients received penicillin postoperatively but in 34 of the 42 cases of perforated peptic ulcer the initial dosage was 100,000 units every 2 hours. Dosage was continued at this level for varying lengths of time—up to 18 days in one patient. The average duration at this level of dosage was 8.5 days. Penicillin was then tapered off through decreasing dosage before being discontinued. Four patients received an initial dosage of 50,000 units of penicillin every 3 hours and the remaining 4 received a still smaller dosage. There were two deaths in this group before the 100,000 units every 2 hours was established as a routine. The usual postoperative regime of support with intravenous fluids and Wangenstein suction was used in all cases.

Of the 97 patients with perforated appendices 71 received penicillin at an initial dosage level of 100,000 units every 2 hours. The duration of treatment at this level ranged from 1 day to 26 days with an average of 5.3 days. Twenty patients received smaller initial dosages of penicillin postoperatively while 6 patients in whom contamination of the peritoneal cavity was minimal received no penicillin postoperatively. There was only one postoperative death, a mortality of 1 per cent among the patients with ruptured appendices and this was due to a massive intestinal hemorrhage on the fifth postoperative day from a crushed and inverted but unligated stump of the appendix.

It is the authors' opinion that inclusion of penicillin therapy in their routine postoperative treatment of perforated peptic ulcers and perforated ap-

pendices has contributed measurably to the low mortality and low morbidity rates for the two groups. Complications due to spread of the existing infection or development of new infectious processes were almost entirely eliminated. In only 1 of the 2 deaths due to a perforated peptic ulcer did infection play a part, and this was an overwhelming peritonitis from the start. The one death from appendicitis was in no way related to the infection. The most noteworthy observation was the absence of wound suppuration in the ulcer group.

EDMUND A. GORVETT, M.D.

Nocturnal Gastric Secretion: Studies on Normal Subjects and on Patients with Duodenal Ulcer, Gastric Ulcer and Gastric Carcinoma. ERWIN LEVIN, JOSEPH B. KRESNER, WALTER LINCOLN PALMER, and CARRIE BUTLER. *Arch. Surg.*, 1948 56 345.

The authors present the results of their studies on the gastric secretion of normal persons and of patients with duodenal ulcer, gastric ulcer and gastric carcinoma. A greater free acidity has been observed in the nocturnal secretion of patients with duodenal ulcer than in that of normal patients.

Studies on the continuous 12 hour nocturnal gastric secretion in normal healthy persons without gastrointestinal complaints have not been reported heretofore.

Studies were made on the nocturnal gastric secretion of 33 normal healthy persons who were known to have no gastrointestinal complaints. 21 of the subjects were males and 12 were females.

There are statistically significant differences between the gastric secretion of normal persons and that of patients with duodenal ulcer, gastric ulcer and carcinoma, although as one would expect, there is no overlapping.

The volume of the continuous nocturnal gastric secretion in the group with duodenal ulcers was found to be significantly higher than that in normal subjects. Comparison of the normal group with the small series of patients with gastric ulcer and gastric carcinoma indicates that there is no significant difference in the volume of gastric juice secreted by normal subjects and by those with gastric ulcer. Patients with gastric carcinoma tend to secrete a lower volume of gastric juice than that secreted by normal persons. The continuous nocturnal gastric secretion in patients with duodenal ulcer is much greater than that encountered in patients with gastric carcinoma or gastric ulcer. Patients with gastric ulcer usually secrete a greater volume of gastric juice than do patients with gastric carcinoma.

Similarly, the free acidity of the total nocturnal gastric secretion is much higher in patients with duodenal ulcer than in normal subjects. On the other hand the free acidity tends to be lower in patients with gastric ulcer and gastric carcinoma than in normal persons. The free acidity of the nocturnal gastric secretion tends to be higher in patients with gastric ulcer than in patients with carcinoma.

The differences in gastric secretion in the groups studied are most evident with regard to the total amount of hydrochloric acid secreted during the night. Those with duodenal ulcer secrete a significantly greater amount of hydrochloric acid than do normal persons. On the other hand normal persons secrete more hydrochloric acid in the nocturnal gastric secretion than do patients with either gastric ulcer or gastric carcinoma. In both instances the differences are significant. Patients with gastric carcinoma tend to secrete less hydrochloric acid than do patients with gastric ulcer.

The results also indicate a wide individual variation in the volume of gastric secretion and in the output of free hydrochloric acid, even in the same person. However if the correlation coefficient is computed, it becomes apparent that a person with a high secretion on one night will in the majority of instances have a high gastric secretion on successive nights. The same constancy is demonstrated by persons with a low secretory rate.

The great difficulty in ulcer therapy is the control of excessive continued nocturnal secretion. Dragstedt maintains that "the chief abnormality of duodenal ulcer patients lies not in the fact that they secrete more gastric juice in response to the stimulus of histamine or alcohol than do normal individuals, but rather in the fact that they secrete large volumes of highly acid gastric juice when there is no known stimulus to the gastric secretory mechanism. The present data quantitatively confirm these observations with respect to duodenal ulcer (not for gastric ulcer) and are similar to those obtained in the studies of Dragstedt and his co-workers. The two studies were carried out under the same conditions. In a previous investigation Levin, Hamann, and Palmer found that for 28 patients with uncomplicated duodenal ulcer the average volume of the continuous nocturnal gastric secretion was 1130 c.c., with an average free acidity of 62 clinical units.

The earlier work differs from the present one in two respects: first, all the patients had uncomplicated duodenal ulcer whereas 6 of the present group had abnormal gastric retention; second, all the patients in the earlier study were placed on a Sippy regimen while the tests were being made, whereas in the present investigation the patients were given a clear liquid diet. Nevertheless the average volume and the average free acidity were similar in the two groups, the difference being only 2.0 clinical unit. It can be safely concluded therefore that the average volume of the continuous nocturnal gastric secretion in patients with duodenal ulcer is between 1,000 and 1,500 c.c. and that the average free acidity is between

bleeding ulcers but a fair proportion of them may be salvaged by timely surgery.

If one accepts this fact, then two alternatives suggest themselves. One is to operate early upon every patient in whom there seems to be any possibility however remote that the hemorrhage may prove fatal. The other is to limit emergency operation to those patients who seem to be bleeding to death. This latter is the course followed by the authors.

The selection of patients for operation depends upon the rate of bleeding rather than the age of the patient, number of previous hemorrhages, or other various factors. A clinical rule adopted is if the rate of bleeding is such that a stable circulation cannot be maintained with transfusions roughly approximating 1500 c.c. of blood per 24 hours, then spontaneous cessation of the hemorrhage is unlikely and emergency operation should be undertaken.

Knowledge of the source of the bleeding is most important and should be obtained from the history, clinical findings, previous roentgenograms and x-ray examination prior to emergency operation. This is considered a prerequisite for this type of surgery in order to prevent a useless operation.

STEPHEN A. ZIDMAN, M.D.

Results Following Subtotal Gastrectomy for Duodenal and Gastric Ulcer. FORDYCE B. ST. JOHN, HAROLD D. HARTY, JOHN M. FREER, and R. W. SHENSTADT. *Ann. Surg.* 94, 83.

Partial gastric resections were performed in 394 individuals for peptic ulcer from 1936 to 1945 inclusive. The authors compare the value of vagus nerve resection versus that of gastric resection.

There were 336 satisfactory results among 394 patients. The basis for the analysis of the unsatisfactory results is presented along with a table showing the postoperative complications. Two tables show the causes of postoperative deaths. A further analysis of additional cases shows that from 1936 to 1935 the results were satisfactory in 73 per cent of 55 cases. From 1936 to 1945 59 per cent of the results remained satisfactory.

In these decades various operative procedures were carried out for the same pathology. The authors believe that a high percentage of excellent results have followed gastric resection and that resection is a relatively simple procedure in patients under 50 years of age. It must be remembered that after the age of 45 carcinoma must be considered in the diagnosis. The mortality rate from 1936 to 1935 was 20 per cent from 1936 to 1945 it was 22 per cent from 1936 to 1945 it was 4.6 per cent and

tion at operation. Even with fairly small carcinomas total gastrectomy is the procedure of choice. The utilization of the Roux Y makes possible more radical resections of carcinomas located in the cardia of the stomach. The considerable length of free duodenum obtainable, and the adaptability of the jejunum to esophageal anastomosis make it advantageous in transthoracic resection of the lower esophagus and stomach also. The facility of manipulation of the loop of Roux Y makes it useful in palliative procedures for nonresectable gastric cancers as well. Since the technical execution of the anastomosis is easier with the Roux Y operation mortality should be reduced.

Cases illustrating the advantages of the procedure are presented, and technical details are illustrated with twenty drawings. FRANK B. QUINN, M.D.

Intestinal Suction Treatment. S. S. KROOK. *Acta chir. scand.*, 1948, 96: 562.

Five case histories are explained in detail to show the indications for treatment by intestinal suction. The differential diagnosis between obstruction due to strangulation and simple obstruction is very important. The risk in the strangulation cases is markedly increased in direct proportion to the time that suction is used.

The author states that he has used operations in all obstruction cases and is of the opinion that his results are comparable with the best results obtained by suction treatment. Furthermore he sees no reason at present to replace operative treatment with successful outcome by suction treatment in mechanical ileus. He does state however that suction treatment is of value in postoperative mechanical obstruction in general following operations on the small bowel and in nonmechanical obstructions of all kinds. Suction treatment aids the maintenance of fluid balance.

RICHARD J. BENNETT, JR., M.D.

Atypical Crohn's Disease. M. J. BENNETT JONES and G. F. WIGGLESWORTH. *Brit. J. Surg.* 1948, 36: 66.

Atypical Crohn's disease is usually maximal at the termination of the ileum, gradually diminishing in a proximal direction so that the wall of the ileum becomes gradually normal at about 10 to 14 inches from the ileocecal junction. The main modification of the original description is that the cecum and the ascending colon may also be affected. Most surgeons who deal with emergency cases of abdominal disease have encountered the inflammatory phase which causes the symptoms and signs suggesting appendicitis. It is thought that resolution can occur at this stage because many patients in whom the diagnosis was made by laparotomy only have remained symptom-free for a year. The obstructive phase of the disease is less common and may be associated with internal or external fistulas, a gross deterioration in the general condition is the rule in these cases.

From the pathological point of view the disease is not usually difficult to diagnose generally it con-

forms to the classical description of the disease by Hadfield and the diagnosis is made mainly on the macroscopical distribution and the type of lesion together with a histological picture of chronic non-specific inflammation with the exclusion of tuberculosis as far as possible. If atypical lesions are to be found in this disease then difficulties of diagnosis will arise.

The authors present a report of 3 cases of atypical Crohn's disease. Two of them were unusual from a pathologic point of view. CHARLES BARON, M.D.

Anal Ileostomy with Sphincter Preservation in Patients Requiring Total Colectomy for Benign Conditions. MARK M. RAVITCH. *Surgery* 1948, 24: 170.

In a lengthy differential discussion of the operations in current use for the control of ulcerative colitis, polypoid adenomatosis of the colon and Hirschsprung's disease the author recommends anal ileostomy in highly selected cases. Two case histories with x-ray illustrations showing that the patients did well 15 and 2 years postoperatively are presented. Sphincter control and absence of cramps were not obtained for about 4 months after the operation at which time the terminal ileum completed physiological dilatation.

A detailed presentation of the technique is made with many photographs. It is essentially a one stage complete colectomy the pelvic floor being remade over the distal segment of the ileum the latter is sutured to the *in situ* external anal sphincter (The anal mucosa and submucosa have been previously dissected away in a 2 to 3 inch cuff by a perineal approach.) It represents a modified Babcock pull through procedure. The procedure may be done in one stage or in two stages with several months intervening between the abdominal and perineal ileostomy formation.

The procedure offers the most help for patients with ulcerative colitis who need colectomy and permanent ileostomy. JANE C. MACMILLAN, M.D.

A Case of Intestinal Lipodystrophy (Whipple's Disease) Simulating Boeck's Sarcoid. BENJAMIN NEWMAN and RUSSELL H. POPE. *Gastroenterology* 1948, 11: 130.

A case is presented of moderately advanced intestinal lipodystrophy (Whipple's disease) which was mistaken for Boeck's sarcoid as a result of biopsy early in the disease. A brief summary of the theories recorded in the literature is presented.

JOHN J. MALONEY, M.D.

Polyposis (Adenomatosis) of the Colon. PAUL I. HOFFWORTH and DAWEY P. SLAUGHTER. *Surgery* 1948, 24: 183.

The experience of surgeons in the operative management of polyposis is reviewed in this article. Seven new cases added to the tabulation of those reported make a total of 35 cases of polyposis found in the American literature since 1930. Analysis of

these shows considerable variability in the chronological order of the surgical procedures used to accomplish the end results. In some cases the variations were necessary because of manifestations of the disease peculiar to the individual. In others they were caused by failure of the first operator to appreciate the disseminating and premalignant qualities of the disease attention at first being directed to segmental resection. Among all the cases the only two methods resulting in cure were total ablation of the large bowel and external ileostomy or total colectomy and ileosigmoidostomy (or ileoproctostomy) combined with fulguration of the lower segment.

It is apparent that no attempt should be made to hold one method of treatment in favor over the other except as applied to the individual patient. The method which preserves sphincter function is to be preferred provided rigid conditions for its safety are established. Otherwise it probably should be discarded in favor of the other plan.

Total removal of the large bowel is the method of choice if there is indisputable or even questionable evidence of carcinoma of the rectum or lower sigmoid colon. Even those who favor preservation of the sphincteric mechanism in patients with cancer of the rectum probably would not care to precede ileoproctostomy by fulguration of polyps in close proximity to the cancer. Total removal might also be preferred if the rectum exhibits closely set polyps with marked hyperplasia, ulceration, and secondary infection. Under these conditions areas selected for biopsy may not be representative and carcinoma can be overlooked.

Total ablation may be done in one or multiple stages in accord with the health, age, sex, and obesity of the patient, and his course during surgery.

The review indicates that the use of preliminary external ileostomy in patients known to have carcinoma of the sigmoid or rectum is generally undesirable because of the long interval imposed by waiting for systemic adjustment or by management of local complications of the ileostomy before curative resection can be done.

Before it is decided to fulgurate rather than to remove the lower sigmoid and rectum, the presence of cancer should be excluded by careful study of the gross morphology of the mucosa well beyond the rectosigmoid region and of the microscopic anatomy of sections obtained from representative areas. Early carcinoma *in situ* may be difficult to recognize in some cases.

The features distinguishing polyposis of the colon as a disease entity are its tendency to occur in certain families, the diffuse involvement of the colon with polyps and the propensity of the lesions early to undergo malignant change. It can be differentiated from the more frequent occurrence of isolated polyps, cancer and inflammatory diseases of the colon and rectum by a careful history stool examinations, sigmoidoscopy and roentgenologic study after barium and air enemas.

The cure of polyposis depends upon the recognition of this disease entity and its differentiation from other diseases before surgical management is planned. Failure to do this may result in inadequate treatment. Surgery should be directed toward either total ablation of the large bowel or total colectomy and ileosigmoid (ileorectal) anastomosis combined with fulguration of the polyps in the preserved segment.

Early recognition of the disease and the increased amount of surgery that can be performed in one stage because of modern therapeutic adjuncts to intestinal surgery combine to give an improved prognosis in polyposis of the colon. STEPHEN A. ZIEGLER, M.D.

Spreading Ulceration of the Skin Associated with Idiopathic Ulcerative Colitis. E. C. B. BUTLER. *Proc. R. Soc. M. Lond.*, 1938, 41: 474.

Progressive ulceration of the skin is a rare but important complication of ulcerative colitis. In the 2 patients whose cases are reported, the ulceration was severe but it is evident from the literature that all grades of skin involvement may occur in association with ulcerative colitis. Other mild cases have been observed in which the ulcers were not painful and healing occurred rapidly with rest and chemotherapy. In the 2 cases presented, the clinical picture was unmistakable. It is the author's belief that these severe skin lesions may endanger the life of the patient.

The ulceration seems to occur in patients who have suffered from colitis over a considerable period of time. In the author's cases, and in others reported elsewhere, the skin ulceration commenced during a exacerbation of the colitis, as shown by pyrexia, diarrhea and rectal bleeding. Healing of the ulcers appeared to depend on cessation of the active phase of the colitis—following medical treatment in one case and following colectomy in the other. In the second case a relapse of the colitis was accompanied by exacerbation of the skin ulceration.

These facts clearly suggest that the skin lesions are in some way linked with the colitis. It is possible that several factors are involved. First, there may be a deficiency due to a lack of biosynthesis of certain vitamins in the diseased bowel secondly the original skin lesion may be an allergic phenomenon similar to that which originally may have caused the colitis. This view is supported by the fact that in one case the discharge from the ulcer was sterile for several days, which was against a diagnosis of primary bacterial infection. Thirdly, lowered resistance of the patient to infection, coupled with secondary anemia, undoubtedly promotes the incidence of the severe secondary infection which so often occurs in these cases.

In the first case cultures from the lesion were sterile for some days before pyogenic infection occurred. The second patient was not admitted to the hospital until secondary infection was well established. Cultures showed, at various times,

staphylococci hemolytic streptococci *Bacillus proteus* and *Bacillus pyocyaneus*. The lesion begins as a raised red papule which rapidly breaks down to form a small ulcer. In mild cases no further spread may occur but in others the discharge becomes profuse and the ulcer rapidly increases in size. Severe pain is a predominant symptom. The commonest sites for infection to occur are the limbs but any part of the body may be affected. Unless the condition is checked the ulcer may spread until the patient is in danger of death from toxemia and anemia. Spontaneous arrest may take place if there is clinical improvement in the colitis but in severe cases energetic local and general treatment is required to halt the spread of the ulceration. Once the infective process has been healed epithelium rapidly grows in from the edge of the ulcer but skin grafts may be required when the lesion has been extensive.

Severe lesions must be treated vigorously. The first patient nearly died because the diagnosis was not made early enough. If the colitis is in an acute stage medical treatment will probably suffice. Diet should include a high protein content, low residue and plenty of essential vitamins. Oral sulfonamides and systemic penicillin should be given in the author's 2 cases however the results from chemotherapy were disappointing. It is possible that larger amounts of penicillin, say one million units daily might have given a more favorable result. Repeated blood transfusions are essential to combat the secondary anemia. If the patient does not improve ileostomy should be considered. In more chronic cases (as in Case 2) surgical treatment may be required more frequently since the skin lesions may relapse with each exacerbation of the colitis. Ileostomy may be required and colectomy is often advisable. Locally the treatment which appeared to stop the spread of the ulceration was excision of the whole of the edge with a diathermy knife. The result was dramatic pain vanished the edge of the ulcer became clean and clear-cut, and the response to local chemotherapy was good.

At operation the limbs should be raised to avoid considerable blood loss from venous oozing. These patients do not tolerate loss of blood and every effort should be made to prevent undue hemorrhage. Blood transfusion is advisable during the operation. Excision with an ordinary knife may be equally satisfactory, but the diathermy appeared useful in the prevention of blood loss. Complete excision of the whole ulcer including the base followed by immediate skin grafting may be successful. Postoperative therapy consists in repeated application of penicillin sulfonamide powder with early skin grafting if necessary. CHARLES BARON M.D.

Congenital Obstruction of the Colon in an Adult
DOUGLAS K. REID *Brit J Surg* 1948 36 52

A case is described in which chronic intestinal obstruction in an adult was found to be caused by two congenital diaphragms of the ascending colon.

The commonly accepted etiology of both atresia and stenosis concerns the epithelial proliferation which takes place in the second month of fetal life to the extent of obliteration of the lumen, which later becomes re-established by absorption of excess tissue. Incomplete reabsorption can readily be understood to leave behind such diaphragms as are described in the present case.

Congenital occlusion of any part of the gastrointestinal tract is an extremely rare cause of symptoms in adult life. CHARLES BARON M.D.

Urologic Complications of Left Colon Surgery
CLARENCE G. Bandler and PHILIP R. ROEM *Ann Surg.*, 1948, 128 80.

Urologic complications of surgery of the descending colon particularly in abdominoperineal resection are more frequent than is commonly acknowledged. An incidence of 30 per cent of urinary complications would seem to be average and three-fourths of these cases occur in males. The urinary tract complications include injury to the ureter with resultant ureteral fistula, trauma to the bladder causing vesical urinary fistula and vesical dysfunction.

Ureteral damage occurs more often on the right side probably because the surgeon working on the descending colon is more meticulous in identifying the left ureter. When ureteral injury occurs and is at once recognized at the time of the colon surgery, end-to-end anastomosis or repair of the ureteral opening should be made over a splinting catheter, the end of which is passed down into the bladder and removed cystoscopically at a later date when healing has been established.

When bladder invasion by the carcinomatous tissue is found either at preoperative cystoscopy or during operation, the location of the invaded area will determine whether the situation is operable or not. When the dome or posterior wall is involved, partial resection of the bladder may be performed. When the malignancy involves the trigonal area, the prostate or seminal vesicles the condition is usually "inoperable." Inadvertent injury to the bladder wall may occur incidental to the operative procedure on the colon. A suture may be taken through the bladder wall with subsequent necrosis and the production of a vesicle fistula. Conservative management with the use of an indwelling catheter is indicated and spontaneous healing will occur as a rule.

The most common urinary complication is of the bladder which is unable to empty itself which becomes infected or both. This is due to (1) injury of the autonomic nervous system during excision of the distal colon (2) direct trauma to the bladder (3) prostatic obstruction or (4) postoperative sagging of the bladder.

Postoperative management consists of insertion of a soft self-retaining catheter 16 to 18 F., for about 5 days. If at the end of this period residual urine in excess of 100 c.c. is noted the catheter should be reinserted. Sulfadiazine (gm 0.5) every 4 hours with an equal amount of sodium bicarbonate should

be given to combat the inevitable infection. If vesical neck obstruction is present transurethral resection should be performed.

ELY ELLIOTT LAZARUS, M.D.

The Role of Hypertrophy of the Muscularis in the Delayed Onset of Symptoms in Cancer of the Colon. JOSEF ARNOLD GRUB. *Surgery* 1948, 24: 221

Struck by the fact that carcinoma of the colon can progress to an incurable stage before the patient (even a fellow surgeon) becomes aware of his trouble Grub undertook a study to elucidate the reason for this lack of symptoms. A perusal of the literature showed that Nothnagel had ascribed the absence of symptoms to hypertrophy of the colon. Experimentally Hertzfel had shown that detectable hypertrophy of the muscles resulted from incomplete obstruction after 5 days while grossly visible hypertrophy was observed in 9 days. It was emphasized that hypertrophy and not hyperplasia is the essential change.

Although Morrison and Saint (1935) as well as Osgood (1940) had discussed the principle of muscle hypertrophy and compensation as it applies to stenosis in hollow viscera and stressed its fundamental importance this concept has been either forgotten or regarded as of only academic interest. In fact, no reference to this work is made in textbooks and standard works pertaining to medicine and surgery.

During the past year Grub studied about 20 unselected specimens of cancer of the large bowel. Inspection revealed gross thickening of both the circular muscle layer and of the longitudinal tenia. This thickening was most marked in the proximal bowel and increased in size as the tumor was approached. There was also some increase in the thickness of the muscle wall below the tumor. Microscopic sections were taken 5 cm from the tumor margin through the wall proximal and distal to the tumor. The muscle layers were increased in thickness without evidence to indicate that edema or cellular infiltration was responsible for this change. The cytoplasm of the individual muscle cells was increased was somewhat paler-staining than the cytoplasm of normal cells and appeared vacuolated. The nuclei were elongated and larger than normal. They were spaced at greater intervals and were hyperchromatic.

Thickening of the muscle coat of the large bowel proximal to a cancer of the colon with stenosis was an impressive finding. The extent of muscular thickening appeared to be related to the duration and degree of stenosis and was the logical result of the increased work demanded of the muscle. It is believed that the effects of the stenosis may be minimized by the increased propulsive power of the bowel wall and thus the symptoms of increasing obstruction are masked for some time. This mechanism of compensation may delay the onset of significant symptoms until curative surgery is no longer possible.

ROBERT TURELL, M.D.

Cancer of the Colon. Elective Surgical Treatment (Cáncer del colon. Elección de operación para su tratamiento) J. GARCÍA MORÁN. *Rev. esp. cir.* 1948, 5: 17

The author discusses the decreased mortality following surgical treatment of cancer of the colon. This improvement is attributed to earlier diagnosis, the use of antibiotics, better general anesthetics, and to the better knowledge of preoperative and postoperative management. He mentions the findings of Puig Sureda of Spain who in 60 colectomies has had no mortality. The author discusses the anatomical innervation of the colon, the incidence of localization of the tumors in the colon, and the common development of cancer in polyps of the bowel.

Different methods of surgical treatment are indicated according to the location of the tumor in the colon. In cancer of the cecum and ascending colon resection of the terminal ileum with the ascending colon and cecum is performed. Tumors of the transverse colon usually are resected and an end-to-end anastomosis is established in cancer of the splenic flexure a transverse colectomy or a colectomy previous to the resection is advised and in cancer of the descending and pelvic colon a resection with an end-to-end anastomosis is carried out.

WILLIAM E. RICKETTS, M.D.

Rectal Prolapse (Prolapso rectal) PARLO H. MYER. *Arch. Soc. cir. hisp.* Santiago 1948, Supp. 6: 3

The author discusses the results obtained with different methods of surgical treatment in 21 cases of prolapse of the rectum. In cases in which the prolapsed rectum presents signs of strangulation, and in which multiple and extensive ulcerations occur in the prolapsed mucosa, or those in which the prolapse is due to a malignant tumor, the elective treatment is either resection or extirpation. In other cases, various methods of colpexy such as the Quenu Duval or Mayo operation or the perianal operation of Lockhart-Mummery were found to be the most valuable.

WILLIAM E. RICKETTS, M.D.

Evaluation of Coloproctectomy and Immediate Anastomosis of the Rectum. R. RUSSELL BERT. *Arch. Surg.* 1948, 56: 68

Forty years ago the objective in extirpation of rectal carcinoma was preservation of the sphincter mechanism and re-establishment of bowel continuity except when the anal canal was primarily involved. At that time a wider excision of tissues in the zones of lymphatic spread accomplished by the more radical abdominoperineal excision including the entire area of the sphincter muscle and establishment of a permanent abdominal colostomy resulted in a decided increase in the percentage of cures. This Miles operation in one or two stages, continues to be the most popular procedure.

Spontaneous attempts are constantly being made to develop a technique which would be sufficiently radical to extirpate all malignant tissue, and yet would preserve the mechanism of the sphincter

muscle. The true basis for the renewed attempts at re-establishing bowel continuity is the study of lymph nodes in this type of malignant condition. This reveals that dissemination of cancer cells of the rectum in a downward direction is unusual unless the nodes above the tumor are blocked by metastases.

The intramural spread of cancer cells below the margin of the tumor also is rare. A clearance of from 1 to 2 inches is usually a safe margin. Laterally lymph nodes extend outward over the upper surface of the levator ani muscle to the hypogastric nodes and cancer cells could spread into these nodes. In lesions situated in the last 3 inches of the rectum removal of at least part of the levator should be considered. With lesions at the 3 inch level or higher in the rectum, the levator fascia and muscle should be excised.

In the evaluation of procedures for preservation of sphincter muscle and function, one must examine the rates of mortality 3 and 5 year survival and morbidity the degree of continence and the element of impotence in males. The incidence of mortality reported in the one stage abdominoperineal resection and in the various types of radical abdominoperineal operations with sphincter preservation varies from a low of 4.9 per cent to a high of 12.1 per cent.

With use of the radical abdominoperineal excision that Miles advocated, the 3 and 5 year cures average about 50 per cent. Satisfactory and comparable results of the sphincter preservation operation however cannot be determined until another 5 or 10 years have passed.

At present it appears that satisfactory continence may be expected in from 80 to 90 per cent of cases in which anastomosis is completed in sphincter saving procedures.

Impotence in males is a very frequent complication following abdominoperineal resection. This complication does not arise as frequently when the sphincter is preserved.

If an operation of the anastomotic type is decided upon one of three procedures may be selected: (1) abdominal dissection, resection and anastomosis, (2) abdominal dissection with perineal resection and anastomosis and (3) perineal dissection with perineal resection and anastomosis. In lesions of the rectosigmoid and immediately adjacent lesions of the upper part of the rectum, dissection and anastomosis can be accomplished from within the abdomen. Likewise lesions lower than the upper part of the rectum—within 2 inches—can be resected and abdominal anastomosis accomplished but lesions at the 3 inch level (midrectal) should have abdominal dissection and posterior resection with anastomosis to insure adequate removal of lymph nodes or infiltrated tissues of the levator ani muscle and fascia. The strongest support for perineal dissection with perineal resection and anastomosis is its expediency in a patient who is a poor risk.

SAMUEL KAHN, M.D.

Resection of Rectum and Rectosigmoid with Preservation of the Sphincter for Benign Spastic Lesions Producing Megacolon

OSCAR SWANSON and ALEXANDER H. BILL, JR. *Surgery* 1948, 24: 212

By the use of special roentgenologic technique it was possible to demonstrate an area of spasm in the rectosigmoid or rectum at the lower limit of the area of dilatation of the colon in 20 patients with a clinical diagnosis of Hirschsprung's disease or congenital megacolon.

The disease was characterized by severe constipation with bouts of obstipation dating back to early infancy and tending to become more severe and distressing as the children grew older. Malnutrition in various degrees was present. The length of bowel involved and the degree of spasm probably account for the variations in the severity of the disease.

In the milder cases treatment with a regimen of mechoyl mineral oil, and enemas was successful. In the severe form of the disease excision of the spastic area of the bowel with re-establishment of bowel continuity offers a satisfactory means of treatment. A method of resection which permitted removal of the rectosigmoid and rectum with preservation of the anal sphincter is described.

After animal experimentation with excellent results 3 children were subjected to resection in which the bowel was divided just above the constricting area. The distal segment was everted through the anus and a small transverse incision made 2 cm. from the anal skin. By means of a long forceps the proximal bowel segment was pulled down and anastomosed to the distal portion the redundant pouch and spastic area being removed. The bowel was then put back into the pelvis the peritoneum sutured about it, and the abdominal incision was closed. Normal bowel movement without the aid of diets laxatives enemas or therapy followed.

It is concluded that the method will be a useful adjunct in the treatment of benign lesions of the rectum and rectosigmoid such as severe spasm. It may have no place in the treatment of carcinoma except perhaps for localized small lesions.

In the technique of the operation the most important step is to be certain that the blood vessels to the proximal end of the bowel are of adequate length to permit the sigmoid to be pulled out through the anus. It is also important that the anastomosis be done in two layers with extreme care to make sure that there be no leakage into the pelvis.

STEPHEN A. ZIEGLER, M.D.

Rectal Cancer and the Preservation of Function

E. G. MUIR. *Brit. M. J.*, 1948, 2: 286

There is a sound pathological basis for operations which aim at preserving a functioning anus in high rectal and rectosigmoid growths but, even in early cases and with adequate excision carcinoma can reappear at the anastomotic site.

To be certain of continence the anorectal ring must be preserved. Of the various methods devised abdominal resection anastomosis and a pull through

resection appear to be preferable. A preliminary transverse colectomy lessens the risk and dangers of infection, and should always be employed.

The use of sulfonamides and penicillin has reduced the mortality with all methods of rectal resection to a low figure. SAMUEL KAHN, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Experimental Repair of Common Duct Defects Utilizing a Free Vein Graft Over Blakemore-Lord Tubes. PATRICK C. SHEA, JR., and CHARLES A. HURAY. *A. S. Surg.* 1948, 8:2.

The treatment of common duct stenosis is difficult in itself but becomes increasingly so when a defect must be bridged. Many methods of repair have been devised using vein grafts, fascial grafts, rubber tubes, vitallium tubes, and adjacent hollow viscera. These methods have not proved completely satisfactory since bile encrustations, contraction, or complete stenosis and obstruction have resulted.

The authors experimented on dogs, bridging common duct defects by the employment of a free vein graft over a Blakemore-Lord tube. It was postulated that epithelialization of the intima of the vein segment with biliary tract epithelium would occur and that the blood supply to the graft would be supplied by vascularization of connective tissue and from peritonization of the graft and surrounding area.

The series comprised 31 dogs, all of which were examined after death or sacrificed at the end of the experimental period. All dogs that survived the experimental period of 10 to 150 days showed the graft to be completely covered with peritoneum, and in 66.7 per cent of the total number of animals the bridging channel remained functionally patent and a free flow of bile was maintained.

ELY ELLIOTT LAZARUS, M.D.

Conservative Therapy of Residual Calculi Following Operations on the Common Bile Duct. GERALD H. AMSTERDAM and JULIAN A. STEALING. *Ann. Surg.* 1948, 53:30.

The authors state that several reports have been published on the occurrence of residual cholelithiasis following operations on the common bile duct. The stones may not have been observed or may have been inaccessible at the time of operation.

These calculi can produce total obstruction to bile flow although the obstructive phenomena are usually incomplete and intermittent. Some stones may disintegrate; others may pass into the gastrointestinal tract through the papilla of Vater or via a fistula; others still may become imbedded in the wall of the papilla or may remain as asymptomatic foreign bodies.

It is advisable to avoid secondary procedures on the biliary tract since the risk of reoperation is great and the technical procedure is frequently very diffi-

cult. Lavage of the common bile duct through an individual "T" tube can be expected to produce excellent results in the therapy of residual cholelithiasis, if given a trial for a sufficient length of time.

The technique consists of irrigating the common bile duct with 3 to 4 c.c. of ether one or two times daily. It should be noted that ether boils at body temperature and this phenomenon may cause discomfort since the expanded vapors can exert considerable pressure. If discomfort occurs the syringe may be disengaged and the ether permitted to bubble out the open end of the "T" tube. Nitrites may be administered for the relief of pain or to relax sphincteric action.

Two cases of residual cholelithiasis are reported. In one of these, daily instillations of ether for a period of 2 months were followed by disappearance of the stone. In the other, instillations were continued for 7 months.

Operative Diagnosis of the Indurations of the Duodenopancreas (Diagnostico operatorio de las induraciones del duodeno-pancreas). LORENZO H. MAR TARELLA. *Praxis med. argent.* 1948, 35:98.

The continuous advances in the diagnosis and treatment of lesions of the head of the pancreas have led to a modification of the topographic concepts of the area, and to the creation of a new anatomic entity, the duodenopancreas which consists of the second portion of the duodenum and the head of the pancreas, and possesses a neurovascular individuality which facilitates the operative diagnosis of indurations of the area and the treatment to be applied. Since tumors as well as inflammations of the area produce similar indurations, the author has endeavored to establish clearly an operative differentiation between them in order to avoid the previously made mistake of performing pancreaticectomy in an inflammatory process. To improve the possibilities of correct diagnosis, any surgeon who performs a laparotomy should also do a routine palpation of the head of the pancreas to enable him to recognize its normal consistency as a result he will find it easier to locate a lesion which has remained silent.

To make a good exploration of the area it is necessary to retract the stomach and liver upward and the transverse mesocolon downward and to palpate the region by inserting the index and middle fingers behind the duodenopancreas (in the diaphragmatic angle formed by the peritoneum on passing from the external aspect of the second portion of the duodenum to the posterior wall) and placing the thumb in front. The normal pancreas has a consistency similar to that of the intestine which surrounds it. When an induration is discovered or suspected, an opening must be made through the gastrocolic epiploic freeing the stomach from the transverse colon in its right half and exposing the duodenopancreas and the remainder of the pancreas.

Once the presence of a pancreatic induration is confirmed it should be classified as being purely pancreatic, or duodenopancreatic or belonging to the region of Vater's ampulla. The symptomatology of each type will furnish information of great interest but the clinico-surgical pictures will be of greater importance. They include

1 Patients presenting symptoms and the diagnosis of biliary lithiasis but without jaundice in whom at operation calculi are found in the gall bladder and a nodular induration is observed in the head of the pancreas. These are cases of chronic pancreatitis secondary to lithiasis.

2 Patients presenting the same symptoms but with jaundice in whom operation reveals gall bladder or choledochus lithiasis with induration in the head of the pancreas either nodular or total, generally elastic and with hardly any increase in size. Cholecystectomy should be performed to make sure that the induration is not due to calculus in which case there is again a secondary pancreatitis.

3 Patients with painless jaundice and a diagnosis of tumor of the biliary or pancreatic ducts in whom the biliary ducts at operation are found to be of normal appearance whether dilated or not, and an induration of the duodenopancreatic area is revealed. The chances are that the induration is due to cancer.

The maneuvers that should be carried out in the exploration of the duodenopancreatic induration are the following: exposure of the duodenopancreas, trocar puncture of the induration, biopsy of the pancreas (this was done in 15 cases), biopsy of peripancreatic lymph nodes, biopsy of hepatic metastases if they are not of typical aspect and exploratory duodenotomy (this was done in 8 cases).

Tumors of the head of the pancreas were observed in 57 cases. They may involve the entire head (this occurred in 45 cases) or only part of it. These lesions develop around the choledochus are called choledochopancreatic tumors, and were found in 11 cases. Those in the lower half of the head called infracholedochal tumors are rare and one typical case was observed. Eight cases of duodenopancreatic tumors were studied. Tumors in the region of Vater's ampulla were found in 9 patients and could be felt by palpation or recognized at the level of the second portion of the duodenum as demonstrated in 7 cases; the other 2 tumors were not palpable and were discovered only through an exploratory duodenotomy.

RICHARD KEMEL, M.D.

Acute Pancreatitis—A Critical Analysis of 15 Cases
FRANK W. BLATCHFORD, JR. and FREDERICK CHRISTOPHER. *Q. Bull. Northwest. Univ. M. School* 1948, 22: 198.

A critical review of 15 cases of acute pancreatitis in patients seen at the Evanston Hospital, Evanston, Illinois from 1938 to 1947 inclusive is given by the authors.

The great frequency with which this disease is associated with biliary tract disorders has been noted. Removal of a diseased gall bladder and of gall stones

is the logical prophylactic treatment of pancreatitis. Four cases of obstruction of the common duct secondary to acute pancreatitis are presented in support of the view that acute as well as chronic lesions of the pancreas can obstruct the common bile duct.

The great importance of the serum amylase test as the only pathognomonic sign of acute pancreatitis is emphasized.

From this study it appears that conservative (nonsurgical) treatment is preferable in cases of acute pancreatitis. Surgical treatment is to be considered in cases of pancreatic abscess and when there is continued and increasing evidence of sepsis.

JOHN J. MALONEY, M.D.

Chronic Relapsing Pancreatitis. R. E. HORTON
Guy's Hosp. Rep., Lond. 1948, 96: 256.

The clinical picture of acute fulminating pancreatitis is well recognized by all physicians; however, the author of this article stresses the point that there is a gradation of severity from the familiar acute phase of the disease to a less often recognized subacute pancreatitis which is characteristically a relapsing disease.

In the course of the inflammatory process pancreatic tissue is destroyed. Healing takes place by replacement of pancreatic parenchyma with fibrous tissue and some regeneration of epithelium also takes place. Successive attacks are followed by an increasing replacement of parenchyma with abscess formation. Impairment of pancreatic function and calcification of areas of fat necrosis are the result of recurring attacks.

The clinical picture may be difficult to recognize and, in typical cases, closely resembles recurrent cholecystitis with cholelithiasis. Recurrent severe upper abdominal pain is characteristic. Jaundice is uncommon and a normal cholecystogram is usual. An elevated serum amylase or lipase is almost pathognomonic of pancreatitis but must only be relied upon early in the course of the disease.

Treatment may be summarized by stating that an operation of internal biliary drainage offers a fair chance of curing the symptoms. Should this be unsuccessful, thoracolumbar sympathectomy may be performed. Pancreatectomy should be reserved for patients suffering from severe pain which is unrelieved by less radical measures.

Seven cases of relapsing pancreatitis are reported by the author. One patient died in a more acute attack; 4 others were treated by cholecystenterostomy and one of these died following operation. The other 3 patients have been relieved—2 completely and 1 incompletely. Two patients continue to be observed.

EDWARD F. LEWIS, M.D.

Tumors of the Spleen and Pseudotumors of the Spleen (Rates tumorales and pseudo-tumorales). EMILIE HOUZE and MICHEL FONTAN. *Bruxelles med.*, 1948, 28: 903.

The authors present 3 similar case histories complete with a microscopic description of lympho-

sarcomas of the spleen representing true primary tumors (Cases 1 and 2) and contrast them with "pseudotumors of the spleen caused by splenic thrombosis (Case 3). In a review of the cases, the authors conclude that there are few clinical clues to decisively determine which type of splenic enlargement is present prior to operation, but an elaborate histologic characterization of the two types of tumors is given.

In the first case a lymphosarcoma, grossly about 14 times normal size was filled with millimeter sized nodules which surrounded the central vessels. The malpighian corpuscles could not be distinguished and the nodules were composed microscopically of lymphoblasts, thus presenting the characteristics of a lymphoblastic sarcoma.

The second true splenic tumor described was also a lymphosarcoma having a similar gross and surgical appearance to the first described lymphosarcoma but the predominant cell type was a small round-cell, uniformly dispersed throughout the organ and comprised of lymphocytes of more nearly adult age.

The third case was one of splenic thrombosis in which the removed spleen was about seven times the normal size and, except for marked hemorrhage on cut surfaces, was not strikingly characteristic in gross pathological description.

Photomicrographs are shown to illustrate a congestive type of splenomegaly without reticular hypertrophy with hemorrhage as the predominant characteristic.

The authors indicate that they have obtained satisfactory surgical results in the removal of true tumors of the spleen, but that the pseudotumors as they term the intrasplenic thromboses can be remedied only if operation is done early before

thrombotic processes have extended into the splenic or portal veins. They believe that there is a considerable latent period in the splenic thromboses of the infectious type which may continue for a considerable length of time before extension develops, this stage of latency being characterized by splenomegaly only. The authors present the idea that this should be considered as a syndrome and an indication for splenectomy before fatal extension of the thrombosis occurs.

JANE C. MACMILLAN, M.D.

MISCELLANEOUS

Experimental Biliary Peritonitis (S 1 coleperitonitis sperimentale). GASPARE BUCCELLATO. *Polidisco* no. 418, 55-53.

Eighteen dogs were divided into 7 series and treated by ligation of the common bile duct, injection of the gall bladder with cultures of the *Bacillus coli*, cultures of the *Bacillus Eberth*, extracts containing pancreatic enzymes, sterile glycerine or combinations of these procedures. The experimental period varied from 7 hours to 33 days.

Histopathological examinations revealed no evidence of the passage of bile through the wall of the gall bladder notwithstanding the presence of edema, necrosis, ulceration, and septic thrombi. Biliary peritonitis was found only in a single animal in which gross perforation of the gall bladder as well as of two intrahepatic ducts had developed. It was concluded that biliary peritonitis does not occur without perforation. The cause of perforation is a constitutional predisposition, with the determining factors of biliary stases, reflux of the pancreatic juices or the presence of infection in the gall bladder.

EDITH B. FARMSTRONG, M.D.

GYNECOLOGY

UTERUS

The Application of a Silver Carbonate Stain for the Diagnosis of Uterine Cancer by the Vaginal Smear Method. H. S. YU, G. M. RILEY, NORMAN F. MILLER, and K. SCHARENBERG. *Am J Obst.*, 1948, 56 468.

The diagnosis of cancer of the uterus by the vaginal smear method is based on the fact that the superficial cell layers of the tumor are subject to early and continuous exfoliation. The malignant cells, once separated from the parent tissue become mixed with the secretions of the uterus and cervix, find their way into the vagina and may be recognized in properly stained smears of the vaginal fluid.

A review of the criteria diagnostic of malignancy indicates that much reliance is placed upon cell conformation, cellular arrangement, and nuclear characteristics. Obviously any stain or combination of stains which would uniformly delineate cellular outline and afford contrast between the nucleus and cytoplasm could be satisfactorily applied to the vaginal smear technique.

The silver carbonate stain method of Hortega was modified for staining the cellular elements of vaginal smears. The affinity of chromatin material for the silver stain together with the usual hyperchromatic character of atypical cells makes this a useful stain in the diagnosis of cancer by the vaginal smear method.

JOHN R. WOLFF M D

Aspects in the Treatment of Vulvar and Cervical Carcinoma. GRACE C. DOWNLEY and W. A. G. BAULD. *Am J Obst.* 1948, 56 494.

This report is a survey of carcinoma of the vulva, carcinoma in the cervical stump, and selected cases of carcinoma of the cervix treated by irradiation and surgery at the Radium Clinic, Royal Victoria Montreal Maternity Hospital McGill University Montreal Canada.

Treatment of the inguinal glands either by surgery as recommended by Taussig, or by x ray irradiation as is now being done in this Clinic should be the initial treatment of carcinoma of the vulva and is to be followed by vulvectomy. Local recurrences of carcinoma of the vulva, particularly after vulvectomy have been few. On the other hand subsequent inguinal gland metastasis have not been infrequent.

The reported incidence for true stump cancer at this Clinic is in relation to all cases of carcinoma of the cervix, 4.21 per cent. The incidence in relation to subtotal hysterectomy is 1.2 per cent. Thirty nine per cent of 28 patients with true stump carcinoma were known to have had bilateral oophorectomy with the subtotal hysterectomy and therefore could reasonably be considered to have had no ovarian tissue at the time the carcinoma developed.

There were no cases of true cervical stump carcinoma in stage 1. The majority were in stages 3 and 4.

These figures suggest that the patient may develop a false sense of security following operation and be more prone to disregard subsequent symptoms.

The majority of cases of cervical carcinoma were treated by radium irradiation and panhysterectomy. There was no dissection or extirpation of the glands or other pelvic structures. This group includes stage III cases. The survival rate has been improved by the use of this method. In a selected series treated in this way the 10 year cure rate was 41.6 per cent.

JOHN R. WOLFF M D

ADNEXAL AND PERIUTERINE CONDITIONS

Theca Cell Tumors of the Ovary with a Report of 15 Cases and a Review of the Literature. WILLIAM R. KNIGHT III. *Am J Obst.* 1947 56 311

Fifteen cases of theca cell tumor of the ovary seen at the Wisconsin General Hospital, Madison are reported. These cases were discovered by reviewing all specimens previously called fibroma of the ovary. The distinctive diffuse yellow color seen on section of the theca cell tumors is the best gross diagnostic criterion and was present in all of the cases.

This tumor occurs most frequently in the fifth and sixth decades. 61.5 per cent of the patients being past 50 years of age.

In the one case so analyzed estrogenic substances were found in the tumor. Progesterone was not present in the tumor nor was pregnandiol found in the urine. Although the estrogen produced by the thecoma is small its effect is prolonged and unopposed by the action of progesterone which may account for the symptoms and frequent occurrence of associated conditions such as menstrual irregularities, postmenopausal bleeding, endometrial hyperplasia, adenomyosis, hypertrophy of the myometrium with uterine enlargement, uterine myomas, and endometrial carcinoma.

Uterine curettage should be done in all cases to rule out associated adenocarcinoma of the endometrium.

Conservative surgery is the procedure of choice in the premenopausal patient in the absence of associated adenocarcinoma of the endometrium. In the presence of the latter total hysterectomy is always the operation of choice.

The collected evidence is not conclusive as to whether theca cell tumors represent a distinct histologic type of ovarian neoplasm. This subject warrants further study since the active principle of both theca cell tumor and granulosa cell tumor is estrogen.

JOHN R. WOLFF M D

Solid Teratoma of the Ovary with Report of 5 Cases. EDMUND R. NOVAK. *Am J Obst.*, 1948, 56 300.

Although dermoid cysts of the ovary are common their malignant counterpart the solid teratoma or

teratoblastoma, is decidedly rare. Of the 5 cases reported by the author, 1 was a private one, 2 were from the gynecological service of the Johns Hopkins Hospital, and 2 were from the Lane Home for Invalid Children at the Johns Hopkins Hospital and were the only cases encountered in these institutions in the past 30 years.

The histologic differentiation between dermoid and teratomatous tumors is sometimes difficult. The word teratoma should be confined exclusively to the solid type of tumor and should be considered malignant by definition.

Teratomas are highly malignant neoplasms from 50 to 75 per cent of them terminating fatally. They occur most often in young individuals and are usually unilateral. Although encapsulated they tend strongly to perforate the capsule and spread both by extension and metastasis.

Radiotherapy seems to help very little. The treatment of choice is still radical surgery and deep x ray therapy. In 4 of the 5 cases reported the patients died. In the fifth case it was difficult to say whether the tumor was a teratoma or a slightly malignant dermoid tumor.

JOHN R. WOLFF, M.D.

EXTERNAL GENITALIA

Use of the Vaginal Smear as a Screening Test.

HERBERT L. LOWMYER, MARGARET MUNDLSTON, SHELDON WARREN, and OLIVE GATES. *N. England J. M.* 1948, 39: 3-7

This article is a preliminary report on a study being conducted by the Massachusetts Department of Public Health to evaluate the vaginal smear method of cancer diagnosis. In a 2.5 year period 3,586 women were examined. There were 434 patients with a known history of uterine cancer, 123 patients with known cancer in the organs adjacent to the genital tract, and 153 patients in whom the smears were unsatisfactory for examination. Of the remaining 2,876 patients 1,364 gave symptoms suggestive of gynecologic disorders, and 1,512 had no symptoms.

From the 1,512 patients without symptoms there were 8 positive smears, but only 3 were confirmed by biopsy. From the 1,364 patients with gynecologic symptoms there were 133 positive smears, 89 confirmed by biopsy. In 27 a clinical diagnosis of carcinoma was made without biopsy. There were 27 patients in whom a diagnosis of carcinoma could not be made.

The authors review the results in the large series of cases presented by Papanicolaou and Traut, Meigs and Gates and Warren. The errors encountered show that a false negative diagnosis is made from 5 to 20 times more frequently than a false positive diagnosis. Careful re-evaluation of the smears which were only suggestive showed errors in diagnosis. However the smears which showed atypical but not distinctly malignant cells were reported and biopsy was recommended. There were 261 cases in this category but the follow-up has not been of sufficient time to

show whether these will eventually be premalignant lesions.

The authors believe that the vaginal smear method will not bring out many cases in apparently well persons, but that its use has widened the understanding of the early symptoms and signs of carcinoma.

GEORGE B. BRADFORD, M.D.

Primary Melanoma of the Vagina, with a Review of the Literature. ROBERT A. MISO, VICTOR H. MISO, and ROBERT G. LIVINGSTON. *Am. J. Obst.* 1948, 56: 3-5.

A case of primary melanoma (melanosarcoma) of the vagina in a 28 year old housewife is reported from the Protestant Deaconess Hospital, Evansville, Indiana. This patient was first seen in May 1944, because of a persistent yellow vaginal discharge occasionally streaked with blood during the preceding 10 month period. Pain in the vagina and bleeding also followed coitus. Examination revealed a superficially ulcerated nonpigmented, rounded, flat tumor 3 cm. in diameter about 1.5 cm. within the vaginal introitus on the midpart of the left lateral wall. Removal of this growth was done and the pathologist reported a benign glandular tumor of the vagina.

Thirteen months later a recurrence was discovered just anterior to the operative scar. Excision of this tumor followed by pathologic study revealed the melanoma. Radical surgical treatment consisting of excision of the local growth, followed by vulvectomy and radical dissection of both groins was performed.

Seventeen previously recorded cases are also reviewed. Radiation was not used because of the poor results obtained in other cases.

Eighteen months after radical surgical therapy this patient is alive healthy and free of this disease.

MISCELLANEOUS

Dysfunctional Uterine Hemorrhage (Hemorrhagia uterina dysfunctionalis). ROBERTO PECORELLI. *Rev. med. Rosario* 1948, 38: 363.

The absolute frequency of dysfunctional uterine hemorrhage is difficult to evaluate since many patients are not hospitalized, but it is variously given as from 0.8 to 7 per cent. More than 50 per cent of the cases occur in the premenopause (40 to 50 years of age) 10 per cent in puberty and adolescence and from 3 to 35 per cent during sexual life. The etio-pathogenesis must be considered separately for the anovular or monoovular hemorrhage and for the ovular or biphasic hemorrhage. For the first, especially the hyperplastic variety there is a rather clear and well established concept of the determining causes (hypophysis-ovary-endometrium complex) although the ultimate mechanism through which the hemorrhage is produced has not yet been cleared up. For the second which has recently been described the causes are still obscure. It may be stated that the first must be considered as an endometriopathy

of ovarian origin either primary or secondary to hormonal changes (primarily antehypophyseal), in which the degree of sensitivity of the endometrium to the ovarian hormones also plays its part. This sensitivity depends upon whether the hemorrhage results from an atrophic or a frankly hyperplastic estrogenic endometrium.

In anovular hemorrhage the ovary presents sometimes a single large cystic follicle the layer of granular cells is well preserved and in some cases there is a living ovule. More frequently there are numerous small follicular cysts. The corpus luteum is usually absent. In ovular hemorrhage the ovarian condition has practically not been evaluated and it can only be stated that among 11 patients studied there were 2 in which the corpus luteum was reduced and the cells were loaded with fat.

The histopathology of the endometrium in dysfunctional uterine hemorrhage is particularly interesting. On the basis of extensive studies the endometrium has been classified into estrogenic or proliferative, progestational or secretory and mixed. The statistics of 10 authors who reported on 922 cases show that the distribution of the three types was 74 per cent for the first, 22 per cent for the second and 4 per cent for the third. The authors' 31 personal cases give a similar proportion.

Age has a certain relationship to the incidence of the three types. Above 40 the estrogenic type and above all the hyperplastic type is very frequent, below 40 the progestational type is frequent. This was confirmed in the author's series. In puberty the hyperplastic type is common. There is also a certain relationship between the type of hemorrhage and the histologic type of the endometrium: metrorrhagia is more frequent in the estrogenic endometrium while menorrhagia is usually associated with the progestational or mixed endometrium. Each of these basic types is subdivided into more or less important subtypes.

The histopathology of the endometrium is of great importance in the orientation and control of the hormonal treatment of dysfunctional uterine hemorrhage. It is especially important for the decision as to when the treatment should be stopped after a final curative effect is obtained which is determined by the spontaneous production of an endometrium with a terminal secretory phase. For this purpose it is best to obtain endometrial material by curettage and aspiration. The study of vaginal smears provides additional data and although in adolescents and virgins they cannot replace endometrial biopsy, they help in the orientation of treatment.

Only 5 fatalities from dysfunctional uterine hemorrhage have been reported. In the 2 patients who were studied histologically the endometrium was atrophic.

Despite the severity of the metrorrhagia and the presence of blood clots the hemorrhage is nearly always painless. It is often preceded by periods of amenorrhea of from 5 to 8 weeks giving rise to the

clinical variety called the postabortive type. The menstrual history and a negative general examination, the absence of organic pelvic lesions or the presence of lesions which do not justify the hemorrhage, and the finding of secondary anemia suggest the diagnosis of dysfunctional uterine hemorrhage. Confirmation is provided by curettage and histopathologic examination of the material recovered. In some cases it will be necessary to take recourse to hysterosalpingo-contrast radiography. At present hormone determinations are insufficient and give discordant results. Basal metabolism determination is useful.

Spontaneous cure is possible especially in puberty or adolescence in which it occurs in from 30 to 80 per cent of the cases. During sexual life there is a possibility of spontaneous ovulation followed by pregnancy and definitive ulterior readjustment in the premenopause there is a possibility of extinction of the ovarian function with final amenorrhea.

A table summarizing the therapeutic orientation advisable in accordance with the genital age of the patient is appended. RICHARD KRELL, M.D.

Prolapse of the Vaginal Parietes and of the Uterus.

Etiology, Pathogenesis, and Treatment with the Report of Cases from the Obstetrical Clinic of the University of Turin (Il prollasso delle pareti vaginali e dell'utero. *Eziologia, patogenesi e cura con contributo casistico dal materiale della Clinica Ostetrica dell'Univ. di Torino*). TIMOTEO NOBILIZ, *Ginecologia Tor.*, 1948, 14, 49.

The occurrence of prolapse of the uterus in children and virgins is usually due to constitutional disorders, e.g. the case reported by Cappellani in which rachitis was the etiological factor. In older people this condition is found among women who have borne children, therefore the etiological factor must be found in the anatomical changes which are brought about by labor.

A meticulous anatomical description of the uterus and its adnexa is given and it is believed that the pelvic diaphragm and the urogenital trigone are the important structures that support the uterus, the muscles being only secondary.

The author agrees with Gaspari and Morra that, during parturition these structures hypertrophy and become hyperplastic and edematous. This softens and weakens the pelvic diaphragm muscles and perineal fascia and causes a diastasis of the levator ani muscle, 1 to 4 cm. in width. As a result of these changes cicatricial adhesions with the surrounding tissues develop in the posterior wall and cause a shortening of the perineum with destruction of the superficial aponeurosis, almost total disappearance of the perineal fascia, and atrophy of the transversus muscle. Histological studies of these tissues in women with prolapse show regressive changes of the muscles, i.e. granular degeneration of the contractile substance with partial or complete disappearance of the neurofibrillae and at times also fatty degeneration.

The author reports 48 cases which were followed for a period of 3 to 10 years. The ages of the patients varied between 26 and 68 years, and all had (1 to 10) children. In his endeavor to explain the presence of prolapse in young as well as older people in uniparae as well as in multiparae the author agrees with Delle Chiaie that the first clinical manifestation of the altered statics of the pelvic organs is to be found in the descent of the anterior vaginal wall and along with it, of the bladder. Because of its proximity to the genital hiatus the bladder will be found relaxed in all women who have borne children, the degree of relaxation depending on the number of children born, the presence of perineal lacerations and the age of the patient. Concomitant with the relaxation of the bladder there is a descent of the anterior vaginal wall first, and later of the uterus which will stretch and ultimately destroy the tonicity of the uterine ligaments. From then on the uterus will continue its downward descent because of its own gravity.

Other factors leading to prolapse of the uterus are minute perineal lacerations not apparent at the time of delivery, a lacerated perineum not repaired, and if repaired, not well healed, and endoabdominal pressure on this locus minoris resistentiae caused by prolonged standing. When lacerations of the perineum are not the cause of the prolapse constitutional muscular weakness must be considered as the etiological factor.

The mechanism of the prolapse is described by the author as follows. The abdominal viscera normally exert pressure on the posterior facies of the normally antiflexed uterus. Pressure on the uterine neck is counterbalanced by the round ligaments. The uterine body rests on the bladder, the vesicovaginal fascia, the pubococcygeal part of the levator ani primarily and on the perineal muscles secondarily. Any unnatural strain which causes a contraction of the diaphragm, abdominal muscles and pelvic diaphragm causes also a contraction of the pubococcygeus muscle. With the contraction of the latter there is a reduction in the fissure formed by the pelvic

diaphragm. In the presence of perineal lacerations there is a lack of support of the neck of the uterus, and the uterus assumes an intermedial or a retroflexed position. The intra-abdominal pressure is now exerted on the anterior uterine facies and the neck of the uterus "threads" so to speak, the genital hiatus. Lack of support causes a pull on the ligaments which, in time lose all resistance and lengthen. From then on the uterine descent becomes progressive unless the condition is corrected surgically. The author advocates the operation of Pentalon which gives the best anatomical results and does not alter the genital and sexual functions of the patient.

JOSEPH M. A. PAPP, M.D.

Gynecologic Surgery in the Elderly with Special Reference to Risks and Results. FREDERIC D. ZIMMAN and ARTHUR M. DAVIDS. *Am J Obst* 1948, 56: 440.

The increasing numbers of elderly women presenting a variety of gynecologic disorders bring new responsibilities to the gynecologist and to the internist.

This study of 302 cases of women over 60 years of age who were subjected to 217 surgical procedures with only 3 deaths indicates that the range of surgery may be extended for this age group.

Careful preoperative studies of these patients by the team of gynecologist and internist sharply limited the operative risk. These elderly women presented a variety of systemic conditions associated with the local lesions. The implications of hypertension, arteriosclerotic heart disease, anemia, diabetes and malnutrition are discussed in relation to determination of the surgical risk.

Modern methods of anesthesia, the liberal use of whole blood transfusions, early rising and the use of chemotherapy and antibiotics prevented or modified complications in the postoperative period.

Careful evaluation of the functional capacity of older individuals will eliminate false emphasis on chronological age and thus point the way to successful therapy.

JOHN R. WOLFE, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Pregnancy Test. CARLOS GALLI MAININI. *J Am M Ass* 1948 135 121

The author's studies indicate that gonadotropic stimulation in the male batrachia has a direct effect on the testicle in which its targets are the interstitial cells the spermatozoa and the Sertoli cells. The presence of spermatozoa in the batrachian urine (migration to the bladder) is indirect proof that the injected substances have acted on the Sertoli cells. The reaction develops quickly. It is specific for some gonadotropins and the response is slightly different when chorionic, serous or pituitary gonadotropins are injected. The Sertoli cells react quickly to gonadotropins.

The phenomenon of detachment and migration of the spermatozoa to the urinary bladder has a practical application in the diagnosis of human pregnancy. The presence of spermatozoa in a drop of toad's urine a few hours after the subcutaneous injection of 10 c.c. of urine from a pregnant woman indicates a positive result. Accumulated data in pregnancy tests in 2 661 cases showed correct results in from 98 to 100 per cent of the cases and an exact negative response in 100 per cent of 1 166 cases in which control tests were made with urine from non-pregnant subjects. This pregnancy test has the advantages of specificity simplicity speed of reaction clear end point, and economy (the same toad can be used again after an interval of a week).

A modified technique of this test has proved to be useful for quantitative gonadotropic determinations.

ROBERT TURNELL, M D

A Further Follow Up Study of Eclampsia. LEON C. CHERNITZ, WILLARD H. SOMMER, and FELIX H. VANDER. *Am. J. Obst.*, 1948, 56 409.

In the whole experience of the Margaret Hague Memorial Hospital, Jersey City New Jersey through 1945 there have been 245 cases of convulsive and 3 cases of nonconvulsive eclampsia, making an incidence of 0.3 per cent. The immediate maternal mortality was 10 per cent and the fetal loss 33 per cent.

All but 2 of the survivors were followed up for at least a year or until death. All but 8 were re-examined in 1946. In 1940 141 of these patients were seen, and all but 5 of these were rechecked in 1946.

There were 12 late deaths 6 of which were associated with cardiovascular renal conditions. The late annual death rate in the immediate survivors of eclampsia was $2\frac{3}{4}$ times the expected death rate.

The incidence of hypertension was 15 per cent. An additional 7 per cent of the patients had elevations of either the systolic or the diastolic pressures alone. There was no increase in the incidence of hypertension in a 6 year interval among the group checked in 1940 and rechecked in 1946.

The incidence of hypertension in the eclamptics of the last 6 years was found to be less than half of that in the earlier group. This reduced incidence may have resulted from a more radical management of pre-eclampsia.

In 226 pregnancies subsequent to eclampsia the recurrence rate of toxemia in the pregnancies carried to the period of viability was 34 per cent. The gross fetal loss was 20.3 per cent.

Although one cannot make a certain prognosis in individual patients it is possible to assess the probability of recurrence of toxemia if one has certain data concerning the eclamptic pregnancy. The most significant factors bearing upon the prognosis are (1) the initial systolic blood pressure at the first visit and before the onset of toxemia (2) the severity of hypertension (3) the duration of the toxemia (4) the time required postpartum for the blood pressure and urine to return to normal and (5) the ratio of the patients' weight to his height.

JOHN R. WOLFE, M D

Heart Disease and Pregnancy. P. R. C. EVANS. *Guy's Hosp Rep Lond* 1948, 96 194.

The author reviews and studies the case reports on pregnant patients suffering from heart disease who were admitted to Guy's Hospital London between 1938 and 1946. There were 90 patients representing 100 pregnancies. The patients were classified according to the New York Heart Association standards. The type of heart disease was divided into congenital thyrotoxic, syphilitic, and rheumatic.

The article consists of a series of tables in which the author summarizes the study.

GEORGE B. BRADBURN, M D

Diabetes in Pregnancy. PAUL M. RICE and ROBERT M. FAWCETT. *Am J Obst* 1948, 56 484.

This study is presented to enumerate the complicating factors of diabetes in pregnancy as they occur at the Elizabeth Steel Magee Hospital Pittsburgh Pennsylvania. The report is based on a 10 year period extending through June of 1946. Among a total of 31 544 deliveries there were 55 cases of diabetes complicating pregnancy. In one-fourth of the cases the diabetes was first discovered during the pregnancy. The average age of the pregnant diabetic patients was 8 years greater than the average age of all the pregnant patients at the hospital. There were twice as many white diabetic pregnant patients as negro.

Most of the pregnant patients with diabetes had excessive weight gain probably due to water retention. One third of these patients had some type of toxemia. One patient developed eclampsia. Sixty-one per cent of all these diabetics in whom the disease was recognized first during pregnancy had some degree of toxemia.

The average duration of pregnancy was less than full term, although in the majority of cases it was of over 8 months duration. Two-thirds of the patients were delivered vaginally. The weight of the full term infants was above normal. The weight of the 8-month infants approached the normal average weight of full-term infants.

The overall fetal mortality was 28.3 per cent. If all deaths up to the seventh month are excluded the corrected mortality is lowered by 10 per cent. There were no fetal deaths among the deliveries by cesarean section. There were 2 maternal deaths, both of which occurred in toxic cases.

Diabetes alone is no indication for therapeutic abortion. All pregnant diabetics should be closely followed up by both the medical and obstetric services in order that the best form of treatment and the most suitable type of delivery can be chosen.

JOHN R. WOLFF, M.D.

The Necessity for Treatment of Pregnant Syphilitic Women During Every Pregnancy MARY STEWART GOODWIN and MARY STRUBER, F. R.C.S. *Am J Syph.*, 1943, 3: 400.

The authors report on 363 women with various types of syphilitic infection who previously had received metal chemotherapy. These women were observed through 370 subsequent pregnancies in which further antisyphilitic treatment was purposely omitted. Twenty-two women, all of whom were originally treated with penicillin for early syphilis, were observed through 26 subsequent pregnancies in which further antisyphilitic treatment was purposely omitted. Of the 596 infants born of these pregnancies during which the mothers were untreated, 549 (92 per cent) were born alive. Twenty of the 48 infants who were stillborn or miscarried were examined at autopsy. Evidence of syphilis in the fetus was found in none. Of the 549 infants born alive, 83 per cent have been carefully followed up for more than 2 months and more than 70 per cent for more than a year. All of the children followed up were normal and nonsyphilitic.

These data indicate that it is not necessary to administer antisyphilitic treatment to a syphilitic woman during every pregnancy and that there is a high degree of probability that the infant will be normal if maternal treatment is withheld (a) regardless of the stage and duration of the syphilitic infection in the mother at the time of the original diagnosis and treatment and (b) regardless of the interval between the previous treatment and the pregnancy in which it is contemplated that further treatment be omitted. However, the mother should previously have received 4.0 gm. or more of arsenphenamine (or its arsenical equivalent) together with concomitant bismuth or 2.4 or more million units of penicillin (given for early syphilis and this probably holds good for a maternal diagnosis of late latent syphilis as well) and this previous treatment should have been administered during a previous pregnancy or during a nonpregnant interval. Also

the mother should show no clinical signs of active syphilitic infection, and should be seronegative or if still seropositive should have a low titer only (1 to 8 dilution units).

Until further information accumulates, a syphilitic woman should be further treated in any pregnancy in which she herself shows clinical evidence of active syphilitic infection or in which, in the absence of such clinical evidence, she herself has a positive serologic blood test for syphilis in a quantitative titer of 16 or more dilution units.

CHARLES BARON, M.D.

LABOR AND ITS COMPLICATIONS

The Practical Application of X-Ray Pelviography to Clinical Obstetrics. DAVID N. DANKFORTH, Q. B. S. *Northwest Univ. M. School*, 1943, 32: 3.

The author reviews the subject of x-ray pelviography to create a fuller appreciation of its purpose and possibilities on the one hand and on the other hand to discuss its limitations. The article is based on the work of Caldwell and Moloy, but it is not intended to ignore the work of Thoms, Mengert, Steele and Javert, Moir and others.

He first discusses the pelvic variations which are of obstetrical importance. The Caldwell-Moloy classification clarifies these by pointing out the variations in the following pelvic features:

Inlet shape

Width of the fore pelvis

Ratio of the widest transverse to the longest anteroposterior diameter

Ratio of the anterior sagittal to the posterior sagittal diameter

Splay of the sidewalls

Prominence of the spines

Height of the symphysis

Transverse diameter of the outlet

Width of the subpubic arch

Curvature and inclination of the sacrum

The four parent groups of Caldwell and Moloy are discussed and differentiated, namely gynecoid, android, anthropoid and flat, and it is pointed out that rarely is a true type of pelvis encountered but rather that most of the pelvis are mixed types which show not only variations in the pelvic type combinations but also considerable variation in size.

The author next discusses the roentgenographic demonstration of the important pelvic features and points out that any technique which is truly satisfactory should demonstrate all of the above outlined pelvic features and their interrelationship. In addition, it would be ideal if it allowed measurement of the biparietal diameter of the head. The most satisfactory method for determining this latter measurement is by the Caldwell-Moloy method of viewing the stereoroentgenogram with the precision stereoscope. This instrument is not at present available. The method used by the author is a combination of those of Caldwell et al., Thoms, Steele and Javert. The measurements are as follows:

1 Standing lateral at 36 inches with a 10 cm rod between the patient's buttocks

2 The Thoms inlet view taken with the patient in the Thoms semirecumbent position.

3 A subpubic arch film with the patient supine and the tube directed at a 45 degree angle toward the symphysis as the target.

In addition a flat film of the abdomen is valuable in determining fetal age and abnormalities.

The purpose and practical use of x-ray pelvigraphy is to determine cephalopelvic disproportion and to prognosticate the mechanism of labor. Cephalopelvic disproportion cannot be determined unless the measurement of the fetal head can be taken. In the absence of a Moloy precision stereoscope these measurements are impractical. An ineffect but useful subterfuge is used by the author to determine inlet proportion. The effective diameter of the inlet is the diameter of the largest circle that would engage in the inlet. This diameter in primiparas should be 15 cm. larger than the biparietal diameter of the head. In an average sized baby as determined by clinical examination the biparietal diameter is from 8.5 to 9 cm. therefore the effective diameter of the inlet must be at least 10.5 cm. In multiparas the difference in diameter is usually 1 cm. instead of 1.5 cm.

The author discusses at length the prognostication of the mechanism and states that for practical purposes full utilization of available space in the pelvis must be made. To interpret the mechanism one must regard two dicta as axiomatic (1) the biparietal diameter is considered the narrowest diameter of the head, and (2) the occiput, generally tends to rotate to the widest point of the pelvis. In this prognosticating one must take into account the general shape of the inlet, the width of the fore pelvis the ischial spine the inclination of the sacrum the nature of the subpubic arch and the transverse diameter of the outlet.

The interpretation of these factors is important especially in delivering with forceps from the mid pelvic position so that the narrowest fetal head diameter may be brought through the narrowest pelvic diameter. Some of the common mechanisms are reviewed namely

Positions (a) occipitoanterior midpelvic arrest (b) occipitoposterior, midpelvic arrest and (c) occipitotransverse midpelvic arrest

The author's excellent article is a timely review and in addition voices an unwritten plea for the more extensive and intelligent use of x-ray pelvigraphy

BYRON F. HAZZETT M.D.

Pethidine in Labor DONALD BEATON *Edinburgh M J.*, 1948 55: 354.

The apparent effect of pethidine on uterine contractions is to decrease both frequency and intensity. This appeared to happen in 60 patients (66 per cent) but it could not have interfered with the function of the uterus since in this series labor was not prolonged. Pethidine does not appear to shorten labor

It has no serious ill effects on the mother or child except that the incidence of postpartum hemorrhage appears to be increased.

The drug has been used with great advantage to the mothers particularly those who were nervous and excited. There appears to be safety in large dosage no matter when the drug is given in the first stage of labor

CHARLES BARON M.D.

Sulfadiazine and Penicillin Prophylaxis in Cesarean Section R. GORDON DOUGLAS and ROBERT LAMDESMAN *Am. J. Obs.*, 1948 56: 432

The problems involved in the proper management of patients with prolonged labor constitute a major challenge to the obstetrician. Cesarean section appears in some instances to offer the best solution, but at times it has not been performed because of the probability of serious maternal morbidity. A study is in progress at the New York Lying In Hospital, New York City to determine the prophylactic value of the administration of sulfadiazine and penicillin in prolonged labor and other complications in which infection may be anticipated.

The results so far indicate that the combined prophylactic use of sulfadiazine and penicillin in cesarean sections has contributed to a reduction in the severity of intrauterine wound and peritoneal infections. With early prophylactic drug therapy a longer trial of labor may be continued without danger. The control of infection by these agents broadens the safe employment of transperitoneal section and reduces the need for extraperitoneal section and cesarean hysterectomy. These drugs may be administered without serious toxic reactions during labor and the puerperium. Urinary tract infections associated with prolonged labor and cesarean section have been drastically reduced. The prophylactic therapy has decreased infantile mortality.

Penicillin and sulfadiazine may act together in increasing the total bacteriostatic activity against a single infecting agent their effectiveness together covers a wide range of bacteria

JOHN R. WOLFF M.D.

A Short or Shortened Umbilical Cord as an Indication for Cesarean Section and Other Obstetrical Operations (Über die durch zu kurze oder verkürzte Nabelschnur bedingte Indikation zum Kaiserschnitt und zu anderen geburtshilflichen operationen) FRANK KURHBACHER. *Geburtsh. & Frauenh.* 1948, 8: 372

The author considers the problem of a short or shortened umbilical cord or both as an indication in itself for operative delivery. He admits the occurrence is a rare one.

Four cases are presented. All of the parturients had pelvis smaller than normal. The infants weighed from 3 000 to 3 600 gm. In each instance but one the cord was considered to be somewhat short (from 40 to 43 cm.) and was wrapped around the neck at least once. Two women were delivered by cesarean section 1 woman by internal podalic

version and extraction and the last by high forceps. There was no cephalic molding of the babies born by cesarean section. All 4 children were delivered alive.

The diagnosis is of necessity difficult. However six signs are listed (1) a funic souffle (2) a "dent" in the uterine wall at the placental site, (3) irregular and severe labor pains, (4) arduous descent of the fetal head, (5) upward withdrawal of the head at the decrement of the uterine contraction, and (6) fetal heart sounds audible on the "rounded" rather than the "flattened" side of the uterus (when the cord is wrapped around the fetus because the back of the child is flattened against the placenta).

The author concludes that with nondescent of the head with or without evidence of fetal distress a cord of insufficient length to permit spontaneous delivery should be considered. Operative delivery is indicated when such a situation is strongly suspected.

WARREN R. LAXO, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Histologic and Clinical Findings in Late Puerperal Bleeding (Histologische und klinische Befunde bei Spätwochenbettblutungen) HANS LINSBURG
Geburtsh. & Frauenk., 1943, 8, 352.

Bleeding occurring late in the puerperium offers many possibilities as to etiology. Older textbooks mention retained placental tissue, decidua or fetal membranes, and endometritis as the most frequent findings in this type of bleeding, but the author after reviewing the writings of others and studying 90 cases of late puerperal bleeding observed in the Women's Clinic at the University in Hamburg, Eppendorf, does not find this to be true.

The author divides his patients into two groups: the first group consists of 41 patients treated in the period from 1922 to 1940, the second, of 49 patients treated in the period from 1940 to 1947.

In the first group macroscopic evidence of placental tissue was found only 4 times (9.8 per cent) and microscopic evidence of placental tissue in the form of a fibrinous polyp was found 5 times (12.2 per cent). Other findings were retained decidua, hyalinization of the blood vessels, endometritis, fibrinous blood clots, irregular proliferation of the endometrium, endometrial hyperplasia, and irregular shedding of the endometrium from a defective corpus luteum. The latter three were considered of sufficient importance to be responsible for the bleeding in 15 instances (37 per cent).

In the second group placental tissue of sufficient size to be recognized grossly was obtained in 13 cases (27 per cent). In 21 cases (43 per cent) it was recognized microscopically. Other causes for bleeding were retained decidua and endometrial hyperplasia; the latter comprising 10.2 per cent. Bleeding from placental fragments occurred usually in the first 4 weeks postpartum.

With late puerperal bleeding, therefore one must consider not only retention of the product of conception but also the endometrium itself.

be hyperplastic or incompletely formed in the proliferative or secretory phase from imperfect follicle or corpus luteum formation. Curettage with histologic examination of the material obtained is necessary to determine the exact cause for bleeding. More over, curettage has therapeutic value.

WARREN R. LAXO, M.D.

NEWBORN

Postpartum Necrosis of the Pituitary T. N. A. JEFFCOATE. *Irish J. Med. Sc.* 1943, Ser. 6, 256.

The author is in total agreement with Sheehan as regards the etiology and clinical features of postpartum necrosis of the anterior lobe of the pituitary gland. He also wishes to emphasize that patients with this syndrome in contradistinction to Simmonds' belief do not show evidence of cachexia until the terminal stages of the process. He believes that Sheehan's estimate of the frequency of the syndrome is slightly high and that the disease is comparatively rare. The rest of the article is concerned with treatment, which is believed to be more difficult than diagnosis. At present the treatment consists of substitution therapy with gonadotropin, corticotropin, thyrotropin, desoxycorticosterone, estrogens and androgens.

Gonadotropins. The author has not had the opportunity of thoroughly testing the effect of follicle stimulating hormone and luteinizing hormone in this syndrome, but he believes that gonadotropin therapy offers more chance of restoring ovarian function in these cases than in any other type of ovarian failure or amenorrhea.

Corticotropin. In general the results are disappointing, but some patients claim they have a sense of improved well being.

Thyrotropin. Preparations of the drug are difficult to obtain and their potency is also doubtful. Thyrotropin has been used by itself with no effect.

Desoxycorticosterone has been used without producing any improvement. It is indicated only in cases with a significant electrolyte disturbance.

Estrogens. With adequate dosages pronounced effects are noted. The vulva, vagina, and uterus lose their senile characteristics and assume those of a woman in the active phase of her reproductive life. Intermittent therapy will produce estrogen withdrawal bleeding. The patients have more energy and gain weight.

gency The author also states that tissue transplants must be considered in therapy but at the present time there has been little success with this procedure The emergency treatment of a patient in crisis consists wholly of intravenous glucose therapy, but vitamins R and C and a high protein and sodium diet are also indicated.

J ROBERT WILLSON M.D

MISCELLANEOUS

Pregnancies after Untreated Sterility of Long Standing (Schwangerschaften nach langjähriger unbehandelter Kinderlosigkeit) KARL JULIUS AM BILAURO, *Geburtsh. & Frauenh.* 1947 7 19

The author discusses in detail a series of 30 cases in which gravidity occurred after many years of sterility without any treatment of either of the partners

He stresses the psychogenic factors in the pathogenesis of functional sterility Especially domestic conflicts with parents or in laws marital difficulties fatigue and worry in business and professional life and financial trouble due to unemployment seem to be causative factors

When it was possible to straighten out these conditions pregnancy occurred frequently without any treatment.

WERNER M. SOLTZ, M.D

Demonstration of Lysozyme in the Amniotic Fluid with Reference to the Bactericidal Power of the Amniotic Fluid (Dimostrazione del lisozima nel liquido amniotico. A proposito del potere battericida del liquido amniotico) G VECCHIETTI *Quad clin ostet gine* 1948, 3 233.

The majority of authors have denied the existence of a lysozyme in the amniotic fluid Vecchietti extracted amniotic fluid by transabdominal puncture from the amniotic sac in 10 pregnant women and tested these samples by the usual method of graduated dilutions for the usual test organism (*Micrococcus lysodeikticus*) which is of course highly lysozyme-sensitive Concurrent identical tests were run against the subject's blood serum

By this method the author finds that lysozyme is present in the amniotic fluid of normal healthy women in the ninth month of pregnancy about one-fourth the amount present in the same subject's blood serum. It is believed that the bactericidal action of the amniotic fluid explains why the amniotic cavity so seldom becomes contaminated from the blood stream of the mother who has bacteria in her blood stream and why infection does not develop intra-amniotically in every case in which the sac has been ruptured.

It is assumed that this bactericidal power of the amniotic fluid also extends to other bacteria many of them pathogenic.

JOHN W BRESNAHAN, M.D

Obstetrical Evaluation of the Pubic Arch W I C MORRIS, *Lancet* Lond., 1948 2 130.

The author presents a clinical method of estimating the availability of the pubic arch for ob-

stetrical delivery A circular metal disc 8 cm. in diameter is used as the measuring device. A metal strip with a centimeter scale is attached to the perimeter of this circle Measurements are made with the patient in the lateral prone position with one leg drawn up The disc is pressed between the ischial tuberosities so that the pubic margin fits snugly The distance between the margin of the disc and the under surface of the pubic arch is measured in centimeters

The author interprets any distance greater than 1 cm. as an indication of narrowing of the arch He suggests that the method is almost as accurate as roentgenological measurement however when narrowing is indicated further study by means of the x rays is indicated The method is apparently more accurate than many others in estimating the angle of the arch and certainly serves to emphasize the importance of knowing the type of outlet with which one has to deal during delivery

GEORGE B BRADBURN M.D

Microscopic Observations of the Placental Barrier in Transplacental Erythrocytotoxic Anemia (Erythroblastosis Fetalis) and in Normal Pregnancy B S. KLING, *Am. J. Obst.*, 1948, 56 226

Microscopic examination of the placenta in 15 cases of erythroblastosis fetalis showed numerous breaks in the barrier associated with hemorrhage from the fetal circulation into the maternal intervillous spaces In areas of very recent hemorrhage nucleated red blood cells of the fetus were observed in the regional intervillous spaces. Regional to the areas of vascular occlusion, the overlying epithelium showed degenerative or necrotic change and in places there was erosion associated with hemorrhage from the fetal circulation into the regional intervillous spaces Coincidentally access of the maternal blood to the fetal circulation was afforded

Microscopic examination of the placenta in the last half of normal pregnancy showed numerous breaks in the barrier of the same type as observed in the cases of erythroblastosis fetalis.

Since it is now known that the erythroblastosis in the disease is a secondary manifestation the designation erythroblastosis fetalis is no longer justified Furthermore it has been found that destruction of the incompatible fetal red blood cells in the disease occurs in part by phagocytosis The term congenital hemolytic anemia therefore is not entirely accurate and transplacental erythrocytotoxic anemia is suggested as a better name for the disease

JOHN R. WOLFF M.D

Contribution to the Study of Ectopic Chorionepithelioma. Chorionepithelioma Situated in the Liver (Contributo allo studio del corionepitelioma ectopico. Corionepitelioma a sede epatica) ARMANDO FASANOTTI *Arch ostet gine* 1947 52 340.

One of the most interesting aspects of the study of chorionepithelioma is that which deals with the ectopic localization of the tumor

The study of these localizations, which may involve various organs without even involving the uterus or uterine tubes broadens our knowledge of the problems concerning the nature and the pathogenesis of chorioepithelioma. This particular tumor loses its restricted significance as a tumor of one organ the uterus, and acquires the more extensive significance of a tumor that might involve widely separated organs.

These tumors occur most frequently in connection with the pregnant state completed or interrupted recent or remote although they may occur independent of the pregnant state as in case of chorioepithelioma of teratogenous origin.

The most common sites of the ectopic localizations of chorioepithelioma are the uterus, vagina, intestine, lung, bladder, broad ligament, and rectovaginal wall. A comparatively rare ectopic localization is the liver. The author could collect only 5 such cases in the literature, and to these he adds a sixth case which came under his observation giving the complete clinical record of the patient and autopsy findings.

The case reported occurred in a married woman 37 years of age who had always been healthy until 5 months before entry into the hospital. Following the delivery of her second child, which was spontaneous and normal in every way she had experienced intermittent low grade fever with chills sensations. The fever was accompanied by a severe type of continuous pain in the right hypochondrium, the pain radiating to the back and the right shoulder and becoming accentuated when the patient lay on her right side. She developed anorexia and general weakness, both of which gradually increased in severity. She entered the hospital in a moribund condition and during the 24 hours prior to her death, she ran an undulating type of fever and developed severe pain in all parts of her abdomen. She vomited several times and was very dyspnoic until death.

Physical examination revealed a moribund patient with signs of right pleurisy. Her abdomen presented a large tumor firm in character and extending from the right hypochondrium to the right iliac crest. The tumor proved to be painful on palpation.

Autopsy revealed a right fibrinous pleurisy. The abdominal cavity contained an abundance of bloody fluid. The liver was noticeably enlarged and weighed 410 gm. It extended downward and transversely to the umbilicus. The right lobe of the liver presented a reddish tumor mass the size of a large apple. The surface of the tumor appeared nodular and irregular. The consistency of the tumor was less firm than that of the surrounding liver tissue. The tumor margins were ill defined, the capsule was perforated in several places. Grossly on section the tumor presented a nodular formation with the appearance

of a bloody sponge, the size of the nodules ranging from the size of a chick-pea to that of a hazelnut.

The uterus was of normal appearance and consistency, but was slightly enlarged. The mucosa was swollen and grayish white in color. The cavity contained a whitish fluid. The body of the uterus and the vagina were normal. Both ovaries contained multilocular cysts. The right kidney contained a calculus.

The anatomopathological diagnosis was that of hemoperitoneum from rupture of a primary tumor of the liver, cardiac decompensation, right fibrinous pleurisy, right renal calculus, and cystic degeneration of both ovaries.

Histological section of the liver showed the tumor nodules to consist of a central and a peripheral zone. The central zone was composed of layers of fibrin, in which there were red blood cells, some of which were of normal appearance and others in various stages of degeneration. Passing from the central zone to the periphery were characteristic neoplastic cells, some in groups and some isolated. These cells were of two types. One type was in the shape of irregularly polygonal cells with clear cytoplasm and small basic-staining oval nuclei. These cells tended to form a membrane. The other type of cells were syncytial cells presenting numerous stages of fusion characteristic of tumor cells. The cell protoplasm was granulated and vacuolated and intensely basophilic. These cells had no characteristics which revealed their origin.

Histological section of the ovaries showed the picture of true corpus luteum cysts.

Histological section of the uterus showed a typical decidua reaction but there were no tumor cells present. Sections of the uterine tubes were normal.

Failure to find evidence of a primary tumor in the uterus, ovaries and tubes shows that the chorioepithelioma of the liver in this case was not metastatic.

There is no structural evidence in the tumor to show that it was of teratogenous origin.

The author believes that this chorioepithelioma of the liver developed from the trophoblastic elements which were progressively dispersed from the decidua uterine. Invading the vessels of the myometrium, these cells passed along through the pulmonary circulation without invading the lungs and came finally to lie in the liver where they developed into the tumor mass. During normal placentation elements of ectodermal origin infiltrate the peripheral myometrium. During decidua reactions in the uterus emboli of trophoblastic elements have been demonstrated in the maternal lungs and liver. In this case the pathological symptoms referable to the liver developed following delivery and progressed rapidly to a fatal termination within 5 months.

BLACKWELL MARKHAM, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Urokiymography (Uroquimografia) ENRIQUE PEREZ CASTRO *Arch. esp. urol.* 1948 4 275

This is a treatise on the many advantages of urokiymography which Castro believes is more valuable than pyelographic studies, serial roentgenography and roentgenographic moving pictures.

Kymography has been applied to cardiac studies and it is thought its advantages here equal those of the electrocardiograph. It is a field little explored at present.

The recording of a moving body in the urogenital system is of inestimable value and urokiymography permits not only this but gives a detailed study of kidney dynamics, particularly of pelvic peristalsis and the normal and abnormal functioning of the calices and ureters. Not only are accessory ureters with or without double kidneys observed, but the functioning of each unit can be determined.

The article has many contrasting illustrations pointing out the advantages of each method of objective study.

STEPHEN A. ZIEGLER, M.D.

Experimental Contribution to the Study of the Behavior of the Renal Lymphatic System Following Partial Subtotal or Total Block of the Lymph Flow and Its Significance in the Pathogenesis of Renal Infections (Contributo sperimentale allo studio del comportamento del sistema linfatico renale in seguito a blocchi parziali, subtotali e totali della corrente linfatica e suo significato nella patogenesi delle infezioni renali) VITTORIO STAUDACHER DALL'ARTE AND BRUNO AMBISANI. *Arch. ital. urol.* 1947 22 236

An experimental study on dogs was undertaken by the authors to investigate the possibility of a renal infection through ascending or descending lymphatic paths. The experiments were performed on 12 dogs under general anesthesia. A suspension of Prussian Blue in turpentine oil was used for the injection of the lymphatics. The experiments were divided into 2 groups: (1) injections into the vesical and ureteral lymphatic reticulum, collecting vessels and external, internal and common iliac lymph nodes and (2) similar injections after the preceding creation of a partial or complete block by means of an occlusion of one lymph vessel, ligation of one or a few afferent lymph vessels or ligation of all lymph vessels leading to the cisterna chyli.

The experiments showed that no connection exists between the intramural lymphatic reticulum of the ureter and the corresponding renal parenchyma. There are communications between the collecting vessels of the upper segment of the ureter and the kidney but, no matter whether normal physiologic conditions prevail or a stasis is provoked, the lymph maintains a centrifugal direction. In spite of a partial subtotal or total block, the lymph flowing from

the kidney maintains strictly the centrifugal direction.

It follows that the propagation of pathogenic bacteria toward the kidney by the retrograde route from remote foci of infection is unconceivable. An inversion of the lymph flow required for contamination of the kidney through the lymphatic paths can be created experimentally only under exceptional conditions which cannot be duplicated in human pathology.

JOSEPH K. NARAT, M.D.

The Pathogenesis of Serous Cysts of the Kidney, with a Personal Observation (Sulla patogenesi delle cisti sierose del rene, con una osservazione personale) P. RIGATTIERI. *Arch. ital. urol.*, 1947 22 157

A 55 year old mother of 8 children who had also had two spontaneous abortions had been suffering from frequency of urination for about a year. About 3 months previously she had begun to suffer with cramplike pains and a sense of heaviness in the left lower part of the abdomen. The examination including a roentgenogram, uncovered the usual findings of a large growth on the left kidney. Nephrectomy brought to light a fetally lobulated left kidney with a serous cyst (size of a child's head) attached rather extensively to its free lateral border and another cyst (size of a hazelnut) protruding halfway above the surface on the anterior aspect of the lower pole. When the kidney was sectioned a still smaller cyst was found just beneath and contiguous to the partially protruding cystic formation.

Histologic examination of all these cavities containing serous fluid disclosed the typical double stratum structure with areas of the inner wall still clothed by endotheliumlike cells. The contents of these cysts was a clear lemon-colored liquid of neutral reaction and with traces of albumin, phosphates and sulphates, but no urea.

The author believes that these cysts were congenital and to be explained on a dysembryoplasmic basis (Ruckert, Kampmeier).

JOHN W. BRENNAN, M.D.

Bilharzial Affection of the Ureter MICHAEL GELFAND *Brit. M. J.* 1948, 1 1228.

The ureter is often affected in urinary bilharziasis. Therefore the purpose of this article is to report on the various lesions found in the ureter in a series of 110 consecutive autopsies on Africans held at the Salisbury Mortuary, Southern Rhodesia.

The literature would appear to stress the obstructive lesions encountered in urinary schistosomiasis. As early as 1919 Fairley drew attention to the tendency of the disease to invade the lower portion of the ureter. He reported that catheterization of such a ureter may reveal a hydronephrosis that has not shown any clinical manifestations. He is one of the early workers to refer to the golf hole appearance

of the ureteric orifice which he not infrequently found involved even in early cases. In another publication Fairley (1919) drew attention to the obstruction occurring in a bilharzial ureter but he also recognized the possibility of a hydronephrosis resulting from obstruction in the bladder wall itself. In his experimental work on infected monkeys he found that the lumen of the lower third of the ureter may show dilatation and the wall considerable thickening. The dilatation results from obstruction due to thickening from the cellular infiltration of the wall in the neighborhood of deposited ova.

Aly Bey Ibrahim (1933) published from Egypt an important article on bilharziasis of the ureter. In it he refers to the very serious complication of stricture of the ureter. Dew (1923) of Egypt infers that the ureter becomes narrowed because of fibrosis and calcification contraction ensuing fairly early in the disease. Hydronephrosis as a result is common. Also from Egypt, Hutchison (1928) refers to an ascending pyelitis and hydronephrosis resulting from stasis of the urine occurring because of obstruction at the lower end of the ureter. Campbell Beggs (1944) writing on schistosomiasis in South Africa refers to the occurrence of a tight fibrous stricture of the ureter which is found only in the minority of cases. Kirkaldy Willis (1946) working in East Africa, mentions the possibility of obstruction in the lower ends of the ureters.

The examinations reveal certain interesting points, and if corroborated by others might cause the present day treatment of bilharzial ureteric disease to be reviewed.

While stricture or stenosis of the ureter is encountered at autopsy this finding is very much less common than the author originally expected. He reported a series of 100 consecutive autopsies in patients affected by vesical bilharziasis and found only one stricture but many dilated ureters. In 1 of the 3 cases showing stenosis in this second series hydronephrosis was present. The author does not state that stricture or stenosis is not serious and does not occur in practice nor that cases of hydronephrosis due to it are not found. However such cases are comparatively rare.

Dilatation of the ureter by the disease is far more common than stenosis or stricture. Such dilatation is usually associated with thickening of the wall of the ureter which also becomes elongated and tortuous. This fact is usually well demonstrated roentgenologically. The functions of such a ureter will become impaired peristalsis will be diminished or lost, and hence urine would not be properly propelled toward the bladder. As a result, stasis will follow and with it some degree of hydronephrosis. This may not be the only explanation of hydronephrosis in cases showing only dilatation of the ureters. Another possible explanation for some of these cases may be a reflux of urine up an incompetent ureteric orifice during micturition when the bladder actively contracts. Because of the dilatation produced by the disease the sphincteric function of

the intravesical portion of the ureter is lost or impaired. The hydronephrosis due to such loss of sphincteric function probably explains some of the cases of hydronephrosis seen in prostatic disease (Hughes, 1946).

When the ureter dilates it also lengthens and "unfolds itself." This "unfolding" may cause the ureter in the particular portion affected to assume an S-shaped curve or bend thus simulating stricture. This was seen in one of the 25 cases reported with dilatations of the ureter. The right ureteric orifice protruded about 2 mm. beyond the bladder mucosa. The orifice itself was dilated (6 mm.). The tube could be passed neither from below nor from above and a stricture was held to be responsible for this. However on opening the ureter the intravesical portion was dilated because of disease. Its circumference being 11 mm. as compared with 8 mm. on the opposite side. The intravesical portion of the ureter had elongated and hence its orifice protruded beyond the bladder mucosa the rest of it had become folded, so to speak, upon itself causing an obstruction.

Recently Barlow, of the Southern Rhodesia Government Medical Service was able to demonstrate such a reflux in one ward case. The patient, an African male passed ova of *Schistosoma haematobium* in his urine and an intravenous pyelogram revealed a well marked dilatation of the lower end of the right ureter. Barlow filled the bladder with "uropac" and then instructed the patient to empty his bladder. An x ray film taken before and after micturition revealed that some of the dye had passed up the ureter from the bladder. There was no evidence of a hydronephrosis on the affected side.

A series of 110 consecutive autopsies were performed on African adults found to have bilharzial disease of the bladder.

In 25 cases the ureters were dilated by the disease. Stenosis or stricture of the ureter was found in 3 cases.

Hydronephrosis was found in 3 cases showing dilatation of the ureters and in one of the cases affected by stenosis of the ureter.

Possible explanations for the hydronephrosis in the presence of dilated ureters are advanced.

JOSEPH L. KIRKPATRICK, M.D.

Ureterocutaneous Transplantation. GEE, SCHMIDT, and GEORGE SEWELL. *J U of Balt.*, 94, 60: 561.

A method of ureterocutaneous transplantation is presented whereby a tubed pedicle is prepared, to enable the terminal segment of the ureter to protrude from the skin and yet remain viable.

Through an oblique skin incision near McBurney's point the muscles are split and the ureter is divided and brought to the surface. A catheter is placed in the ureter, and the wound is closed up to the skin. One of three methods is used in applying skin pedicles. If the abdominal wall is loose as it is likely to be in thin patients, quadrangular skin pedicles are used. Silk is used to close the tube and a steel wire suture is used at the base

The mucosa at the mouth of the ureter is sutured to the skin. If the patient is obese and the skin is taut longitudinal skin pedicles are made bilaterally with parallel incisions.

A third method is to wrap a single longitudinal skin pedicle corkscrew like to form the tube. Following operation the ureteral catheter is fixed in a vertical position with a wire frame.

The procedure described was devised in an attempt to avoid the use of a permanent catheter in the ureter to facilitate gravity drainage of the urine and to avoid stricture formation.

JOSEPH E. MAURER, M.D.

BLADDER, URETHRA AND PENIS

Vesical Dysfunction in Paraplegia. HERBERT S. TALBOT *J. Urol.*, Balt., 1948, 59: 1130.

The major urologic problems encountered in the care of patients with spinal cord injuries arise either directly or indirectly from interference with the normal innervation of the bladder. A prominent exception is the tendency toward urinary lithiasis which is frequently exhibited by patients undergoing long periods of muscular inactivity for any reason but even this is in these cases notably enhanced by the stagnation and infection resulting from the vesical dysfunction. It is of course well known that vesical function which is normal or clinically indistinguishable from normal is restored spontaneously in a significant proportion of cases of spinal cord injury even though paralysis of the extremities may remain. It is probably true as well that if genuine recovery of bladder function is to occur it will occur relatively early perhaps as soon as spinal shock has passed. However spinal shock is itself a phenomenon of variable duration. Sensory and motor return in the extremities is seen 18 months or more after injury and although visceral return may not be anticipated after so long an interval, it is difficult to find logical justification for establishing an arbitrary time limit beyond which no prospect remains but permanent suprapubic drainage.

The bladder is a reflex organ upon which has been superimposed a number of controls exerted by the higher nervous centers which are largely inhibitory in character, with probably an added factor of co-ordination. The normal bladder manifests a striking capacity to adapt its configuration to changes in the volume of its contents. Detrusor contraction is stimulated by stretch only and is associated with a reciprocal opening of the internal orifice which is independent of central nervous control. Inhibition of micturition is a direct mechanism facilitation is indirect and is effected by withdrawal of inhibitory barriers to reflex contraction.

The reflex centers for vesical function are located in the second third and fourth sacral segments of the spinal cord. The efferent supply to the detrusor muscle passes through parasympathetic pathways. Interruption of the sympathetic nerves has no effect upon micturition. The afferent fibers pass through

Fig 1 (Schinagel and Sewell)

both parasympathetic and sympathetic channels some of those in the latter entering the cord as high as the ninth dorsal segment.

Cystometry provides a valuable means for the study of the normal or pathological physiology of the bladder.

The treatment of neurogenic vesical dysfunction after spinal cord injury should not be considered as completed when reflex involuntary voiding has been established. A program of rehabilitation is suggested which in a considerable number of cases will result in urethral voiding little or no residual urine, a useful bladder capacity and a reasonable degree of voluntary control. The methods employed include closure of urinary fistulas, renal drainage, training of the patient to initiate voiding at suitable intervals and transurethral resection in suitable cases.

JOHN E. KIRKPATRICK, M.D.

Plesiorontgenotherapy of Bladder Tumors (La plesiorontgenoterapia dei tumori vescicali) PASQUALE BRUNI. *Urologia* 1948 15: 207

The technique of plesiorontgenotherapy used by the author consists of suprapubic opening of the

bladder and exposure of its cavity by the use of Legueu's retractor. The tumor is lifted with Mari on's forceps for vesical tumors and cut with the electric knife at its base. A field-limiting portal, sterilized by boiling and having a diameter of 25 mm. and a surface of 500 sq. mm., is applied to the cut base of the tumor and kept in place by a forceps, and the extremity of the roentgen tube covered by a sterile rubber finger cot is introduced into the portal. If the portal is too small to cover the entire tumor base two or more fields are used successively. The factors for irradiation are distance 5 cm, filter 0.3 mm. of aluminum kilovoltage, 50 surface dose, 8,000 roentgens per minute. After irradiation, the bladder is closed on a Penzer sound and the abdominal wall reconstructed. Following an adequate period of observation the sound is removed and the opening allowed to close. Cystoscopic control and eventual biopsies are instituted methodically during the post-operative period and subsequently.

Bruni has treated 8 cases in this manner 3 of which have already been reported in 1932. The ages of the patients ranged from 45 to 63 years. The histologic diagnosis was papilloma in an advanced stage of cancerous degeneration in 3 cases and various types of carcinoma in the 6 other cases. The total doses given ranged from 16,000 to 48,000 roentgens, and the number of fields used from one to six. The dose given to each field was 8,000 roentgens except in 3 cases in which 16,000 roentgens were used. No immediate or late or local or general disturbance was observed.

Immediate cure was obtained in all patients except one who died on the third postoperative day from cardiocirculatory insufficiency. Permanent cure must be accepted for the 2 patients who were operated upon 7 1/2 and 6 1/2 years ago, respectively. Local recurrence was observed in 2 patients, 24 and 22 months postoperatively. One patient died from acute intercurrent disease 3 months after immediate cure. Two patients were treated too recently (12 and 6 months ago) to allow speaking of permanent results. It would thus seem that the method deserves further trial because its innocuity must be considered as established. This will allow improvement of the technique and determining the indications on a more secure basis. In the mean time the method should not be used when complete surgical removal of the tumor is possible without complete removal of the bladder. It may be used when it will allow a more economical intervention, as in one of the present cases in which the tumor involved a ureteral orifice and irradiation made ureteral reimplantation unnecessary with immediate and late favorable results. The method should be considered in cases in which the site or extension of the tumor makes partial cystectomy impossible and total cystectomy necessary and also in cases in which the spread of the tumor, the general condition of the patient and the presence of metastases do not allow total cystectomy and make recourse to symptomatic treatment imperative.

RICHARD KIMMEL, M.D.

GENITAL ORGANS

Retropubic Prostatectomy GEORGE AUSTIN, JR.
AND WILLIAM C. QUINBY *N. England J. M.* 1943,
39: 35

Until recently three principal operative approaches to the prostate had been accepted as satisfactory: perineal prostatectomy, suprapubic transvesical prostatectomy and transurethral prostatectomy. No one of these procedures alone is applicable for the treatment of every type of prostatic obstruction. In spite of the contention of surgeons who are strong proponents of one method to the exclusion of the others, it seems fair to say that each of these procedures has certain indications and contraindications, as well as certain limitations and disadvantages, and that each is attended by various technical difficulties that may render the results of operation unsatisfactory. Therefore, when a new and logical method of treatment is proposed, which apparently produces good results in intelligent hands, the progressive surgeon must examine it carefully.

In 1915 Millin of London presented his initial report of a new extravascular technique of prostatectomy—a suprapubic operation for nonmalignant lesions of the prostate to which he applied the name "retropubic prostatectomy." Although Millin considered his operation original, he noted that a somewhat similar suprapubic extravascular approach to the prostate had been made and reported by others. He referred to the reports of Van Stockum in 1909 and of Jacobs and Casper in 1933.

In his initial publication Millin reported the results obtained in 20 patients with benign prostatic disease who were operated upon by this method; 13 of the patients had generalized hypertrophy, 2 had fibrous glands with a sclerotic bladder neck, 1 had calculeous disease, 2 had pure lateral-lobe hypertrophy, 1 had generalized hypertrophy associated with a prostatic abscess, and 1 had postprostatectomy scarring of the prostatic urethra. There were no postoperative deaths, and complications were few. There were 2 cases of minor delayed bleeding, both in patients who had had grossly infected bladders before operation, which was easily controlled by the use of an inflying catheter for 48 hours. No cases of immediate hemorrhage, gross infection, pyelonephritis or renal failure were encountered. A femoral vein thrombosis developed in 1 case and an abscess of the testis in another. In only 3 cases was there suprapubic leakage of urine after removal of the urethral catheter on the sixth or seventh postoperative day and in these cases it was felt that this occurrence was the result of initial faulty adjustment of the catheter. Concerning the long term follow-up results, Millin believed that it was too early to pass a verdict on the incidence of post-prostatectomy obstruction, but subsequent reports from his clinic have shown that postoperative constriction of the vesical neck occurs occasionally. For that reason he has made a modification in his original technique which is described.

In summarizing the features of the retropubic operation the authors believe that the Millin technique is particularly suited for treatment of the following types of prostatic disease: benign hypertrophy of the lateral lobes or of the lateral lobes and the median lobe combined; benign hypertrophy of the median or subtrigonal lobes when intravesical extension is not marked; and calculous disease of the prostate particularly when associated with benign hypertrophy. With increasing experience and future developments in technique this approach may also prove to be a good method of performing plastic procedures in the prostatic urethra and at the bladder outlet.

At present the Millin operation is not indicated for the treatment of patients with obstruction due to sclerosis of the vesical outlet and prostatic fibrosis. In such cases transurethral resection is the preferred procedure. In cases of prostatic obstruction associated with disease of the bladder in which surgical therapy of both lesions is required transurethral resection is preferred also. In this category may be grouped patients with prostatic obstruction who also have a vesical tumor, large vesical calculi, a poorly draining diverticulum with or without tumor, and any other vesical lesion necessitating surgery. And finally for the reasons mentioned before it is believed that the retropubic operation is not suited to the treatment of early carcinoma of the prostate.

The pertinent literature concerning a newly proposed method of retropubic prostatectomy is briefly reviewed, and the advantages and disadvantages of the procedure are discussed.

The indications and contraindications for the employment of this operative approach are presented in the light of a limited experience with the operation.

The technique of the operation is outlined, and a summary of the results obtained in a selected group of 20 cases is recorded.

JOHN E. KIRKPATRICK, M.D.

Estrogenic Hormone Therapy of Prostatic Carcinoma (Ormonoterapia estrogena del carcinoma prostatico). PASQUALE BRUNY. *Gior ital chir* 1943, 4: 296

In 20 cases of prostatic carcinoma observed at the Surgical Clinic of the University of Naples the ages of the patients ranged from 52 to 76 years, and the disease had been present from a few weeks to 9 years. 13 cases were primary carcinomas and 7 were degenerated adenomas. Bone metastases were roentgenologically demonstrated in 4 cases. Epicystostomy was performed in 8 cases and roentgentherapy in 3. Sixteen patients were subjected to active hormone treatment orally or parenterally, and 4 to castration alone. The doses of estrogen ranged from 2 to 15 mgm. per day. The best method is to start with an attack dose of from 3 to 15 mgm. daily and to pass to a maintenance dose of from 3 to 5 mgm. daily. The duration of treatment to date has varied from 31 months to 25 days. In 2 cases suspension of treatment was followed by rapid aggravation, but re-

sumption of treatment allowed the patients to regain what they had lost. In one case the treatment caused attacks of bladder tenesmus which induced the patient to suspend treatment several times; the result of the treatment was negative during the 18 months it was applied.

The results of treatment were favorable in 14 patients (70 per cent), negative in 3 (15 per cent), and unknown in 3. Late results can be considered only in cases in which the hormone treatment has been administered for at least 12 months. Of 6 patients fulfilling this condition, one obtained no benefit but in 5 there was marked improvement. One of these died of extraneous disease after 12 months; another died of uremia and urosepticemia after 22 months; and a third died of gradual cachexia despite 30 months of successful treatment. The last 2 are in good condition after 31 and 20 months, respectively.

Castration performed in 4 patients without associated stilbestrol therapy dates back 6, 5, 3, and 2 months, respectively. Although it is impossible to speak of late results, its favorable results in 100 per cent of the cases stand out against the favorable results in only 62.5 per cent; the negative results in 18.7 per cent, and the unknown results in 18.7 per cent as obtained with hormone therapy. In addition it is to be noted that the systematic favorable results of castration were early and conspicuous, while those of hormone therapy were not so constant, so imposing, nor so early.

From the point of view of the results obtained with hormone therapy, there was no observable difference in behavior between cases of primary cancer and cases of degenerated adenoma.

RICHARD KEMEL, M.D.

MISCELLANEOUS

Transperitoneal Dialysis. RONALD W. REID. *Proc R. Soc. M. Lond.* 1943, 4: 413.

The accumulation of toxic metabolites, alterations in the osmotic pressure of body fluids, dehydration, excessive hydration, electrolyte imbalance, and acid base alterations are a few of the many factors involved in producing the clinical entity called uremia.

The composition of the body fluids is estimated to be: vascular, 3 liters; interstitial fluids, 12 liters; and intracellular, 35 liters for a 150 pound man. These various factors account for about three quarters of the body weight. Interchange between these three types constantly occurs. Potassium and phosphorus are the ions concerned in the composition of the intracellular fluid. Apparently the cell membrane, in contrast to that of the capillary, is impervious to most electrolytes.

The relationship of the kidney to the fluid in the vascular system and the remainder of the extracellular fluid is shown by an illustration. It is apparent that the function of the kidney is to maintain the physical and chemical constancy of the body fluids and to eliminate waste products. On decreased renal function resulting from disease, de-

hydration or lack of salt or other essential factors for proper function change in the body fluids occurs and waste products accumulate. While the exact nature of the change remains in doubt it is known that urea and phenols increase in the blood stream when renal insufficiency exists. While urea, even in high concentrations is not toxic the determination of the urea blood level serves as an index to the severity of the uremia. The basic concept of the treatment of uremia by dialysis is that the physical and chemical composition of the extracellular fluids, excluding protein, can be influenced by contact across a semipermeable membrane whether by means of an artificial kidney or by peritoneal lavage.

The contact with the extracellular fluids achieved by means of the artificial kidney is illustrated.

Four principles are considered to be involved in the treatment of uremia: (1) where possible remove the cause (2) reduce the kidney load (3) substitute renal function by artificial means and (4) relieve symptoms without prejudicing recovery.

A thorough urological survey should be carried out. Protein breakdown should be reduced to decrease the amount of metabolic products to be excreted. Carbohydrates should be substituted for protein. Fluids or diuretics should be avoided since water and urea usually exist in sufficient amounts. Existing anemia should be corrected. Six cases are presented in detail. The first patient received an incompatible blood transfusion treated with vast quantities of parenteral fluids. Anuria developed with an accompanying blood urea of 53 mgm. per cent. Subsequent ineffectual treatment consisted of cystoscopic irrigation of both kidneys under high spinal anesthesia. On the tenth day bilateral renal decapsulation was followed immediately by peritoneal lavage with 2,000 c.c. of twice normal saline solution with a 2,100 c.c. recovery of the perfusate. Simultaneously the patient began to void. A urethral catheter as well as pass urine via the renal dialysis. On repeated days, peritoneal lavage was performed with a total of 6,000 c.c. of twice normal saline solution with recovery of 2,500 c.c. containing 6 gm. of urea. However recovery was attributed to renal decapsulation.

Although peritoneal lavage was not directly responsible for recovery in the second case it was noted that the concentration of urea in the peritoneal fluid was higher than that in the blood. The chloride concentration of the dialyzing fluid increased. The knowledge gained from the preceding 2 cases was applied to the subsequent cases. Normal saline solution was used in the third case instead of twice normal saline solution. With this solution the blood urea was decreased from 203 to 195 mgm. per cent. No ill effects were noted until the fourth case in which similar therapy was employed. Death in this case was from pulmonary edema as a result of overloading the patient with water and chlorides.

Five per cent glucose in water was used as the dialyzing fluid in the fifth case. Intermittent lavage permitted recovery of 385 gm. of urea as well as 32

gm. of chloride. Five per cent glucose in normal saline solution was used as the dialyzing fluid in the sixth case. Although no ill effects were observed from the lavage, recovery as in the previous cases, was attributed to other methods of therapy.

It is obvious from these studies that urea and presumably other toxic products can be removed from the blood stream with clinical improvement, but it is difficult to translate this into statistical terms. The maintenance of the electrolyte balance is most important. Following peritoneal lavage the concentration of urea in the wash may exceed that in the blood stream.

Intermittent injection and withdrawal is safer than continuous perfusion. The fluid used should permit rapid diffusion of the waste products, should not grossly alter the electrolyte and water balance of the extracellular fluids, should have an osmotic pressure near that of plasma and be adjusted to combat acidosis and alkalosis. Peritoneal lavage is advocated in cases of temporary renal suppression when the return of renal function is possible.

PETER L. SCARDINO, M.D.

Dialysis of Blood for the Treatment of Uremia.

E. M. DARMADY. *Proc. R. Soc. M. Lond.*, 1948, 4, 4 B.

Previously encountered difficulties in treating uremia by blood dialysis having been overcome with the use of a cellophane tube and a method of spreading a small quantity of blood over a large dialyzing surface, the author submits his method for the treatment of uremia.

The patient is heparinized with from 200 to 300 mgm. of heparin. In case sudden hemorrhage occurs blood transfusions and protamine sulfate are given. Blood is extracted from the radial artery and controlled synchronized pumps regulate the inflow and outflow. The machine is first filled with compatible blood. The dialyzing tubing is wound around a rotating drum to permit the spread of a small quantity of blood over the dialyzing surface as well as to agitate the blood. By synchronizing the drums to the pump so that 10 ml. of blood enter the machine for each complete rotation a better and more even film is produced. The author's instrument has a series of plates 1/8 inch apart through which a tube of cellophane is led. The flow of dialyzing fluid is arranged by means of a number of small tubes in the plates which allow the dialyzing fluid to flow outward from the center in either direction.

The author believes that failures are due to the dialyzing fluids now available and looks forward to a fluid which will be not only isotonic but also isosmotic.

PETER L. SCARDINO, M.D.

The Artificial Kidney: Its Clinical Application in the Treatment of Traumatic Anuria. E. G. L. BRYANT AND A. M. JOYNER. *Proc. R. Soc. M. Lond.*, 1948, 4, 470.

Lesions of the distal convoluted renal tubule (lower nephron nephrosis) are produced in many ways

vessel rupture muscle rupture electric shock, flogging hemolysis, Welch's infection intravenous water in transurethral prostatic resection intravenous soap in abortion and sulfonamide hemolysis.

It has been demonstrated that after the first week, the affected epithelium is desquamated and excreted in the urine as a cellular coat to the pigment cast with regeneration and mitosis from the basement membrane and finally, diuresis. Prior to the advent of the artificial kidney methods of combating uremia were usually unsatisfactory. While potassium levels could be reduced with insulin by depositing this electrolyte intracellularly, dilution of the protein metabolites with saline solution frequently produced severe pulmonary edema. Purging and sweating did not remove more than an insignificant amount of metabolites.

The artificial kidney is best suited to that case in which recovery of renal function is expected that is one in which either functional disorder or disease affecting the tubules does not involve the glomeruli. The artificial kidney is probably most useful in lower nephron disease.

Details of the 2 cases successfully treated by dialysis are given.

A patient suffering traumatic anuria with a blood urea of 390 mgm. per cent was dialyzed for 5 hours with removal of 32 gm. of urea. The third day after dialysis a secondary rise in blood urea occurred but was overcome by diuresis. The blood urea was decreased by 179 mgm. per cent to 211 mgm. per cent. Recovery was satisfactory.

The second successfully treated case was that of a patient who developed pigment nephrosis fol-

TABLE IV—COMPOSITION OF BATH WATER

Constituents	Concentrations per 100 ml.
600 grams NaCl	Calcium 3 mgm.
1500 grams Glucose	Glucose 1,500 mgm.
200 grams NaHCO ₃	Chloride (as NaCl) 630 mgm.
40 grams KCl	Sodium 390 mgm.
100 liters tap water	CO ₂ (C.P.) 54 ml.
	Potassium 20 mgm.

*Combining Power

lowing anesthesia. After one 4 hour period of dialysis on the twenty-sixth postcholecystectomy day 33 gm. of urea were removed which reduced the blood urea from 424 to 264 mgm. per cent. After that, except for a transient blood urea rise the urine output increased and the renal function as well as the blood urea fell to normal. The author has modified the Kolff apparatus which he describes in detail. The modification avoids the excessive pressures under which the blood was formerly pumped from the machine into the patient's vein. Other technical details are discussed including the composition of the bath water (Table I) and methods for regulating the venous replacement of arterial outflow.

Adjuvant therapy consists of amidopyrine (0.6 gm. 6-hourly for 24 hours) sodium pentothal anesthesia, penicillin, and calcium gluconate. Such substances as thiamine and ascorbic acid have been added to the circulating blood. During the recovery period a high carbohydrate diet has been administered as well as testosterone to increase tubular regeneration. It is suggested that dialysis is applicable in other conditions. Large quantities of aspirin were removed by dialysis from an aspirin poisoning case.

PETER L. SCARDINO M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

The Syndrome Called Osteitis Fibrosa (Die Begrenzung der Ostitis fibrosa) HANS HELLNER *Chirurg* 947 17-8 45 199.

Konjetzky who first differentiated giant cell sarcomas from true sarcomas, pointed out that localized osteitis fibrosa can be found in any bone disease. Le osteomyelitis tumors juvenile cysts, and benign giant cell tumors. The findings of localized osteitis fibrosa indicate only that a tumor or an inflammatory focus in bone caused activation of fibrous tissue within the Haversian spaces. There is usually by peremla which may be on an inflammatory or mechanical basis with an increased formation of osteoclasts. Increased bone destruction initiates bone formation increased numbers of osteoblasts and irregularly dispersed osteoid tissue. The term osteitis fibrosa should be limited strictly to one specific condition. There are eight distinct entities

- 1 Osteitis fibrosa generalisata cystica (Recklinghausen's disease)
- 2 Osteitis deformans (Paget)
- 3 Renal osteitis fibrosa in adults. This disease is identical with that given as number 1. Renal osteoporosis shows no relationship with osteitis fibrosa.
- 4 Juvenile bone cysts.
- 5 Polycystic osteitis fibrosa of one or several bones is part of the juvenile bone cysts and does not require a separate classification.
- 6 Giant cell tumors of early adult life. Cysts and giant cell tumors have some histological features in common
- 7 The so-called polyostotic osteitis fibrosa has nothing whatever in common with osteitis fibrosa. The name precocious puberty with bone dysplasia is a better term.
8. Renal osteitis fibrosa or renal rickets should be considered as a separate entity

A discussion of each entity follows

1 Osteitis fibrosa generalisata (Recklinghausen) is an endocrine disturbance affecting the entire body. The generalized decalcification of the skeleton is based on a disturbance of the mineral metabolism. An adenoma of the parathyroid glands is usually found and may be the cause or the consequence of the metabolic disturbance. The Erdheim theory of secondary involvement of the parathyroids appears to be acceptable. Hypertrophy of the parathyroid glands is found in osteitis fibrosa, osteomalacia, rickets, cancer of bone, multiple myeloma, and osteitis deformans. Hypertrophy of the parathyroid glands usually appears after the demineralization has reached a high level and thus a vicious circle is established. It is the opinion of most authors that an endocrine disturbance of a hypothalamic center causes an acid tide of the metabolism

which is responsible for the decalcification. Later an adenoma of the parathyroid glands plays the leading part in the future development of the disease. There is polyuria and polydipsia. There is hypercalcemia and there is hypophosphatemia. Loss of calcium causes a decalcification of the skeleton and muscle weakness. The weakness of the muscles is manifested by decreased electric excitability and disturbance of the muscle metabolism (hypophosphatemia). There is softening of the bones which causes bowing and fractures. There is evidence of decalcification thinning of the cortices, and widening of the marrow cavity (Decalcification of the skeleton can be noted on the roentgenogram only after 10 per cent of total calcium loss). The changes which made Recklinghausen consider his disease as a cystic degeneration of the entire skeleton are a secondary manifestation.

One must remember that he is observing certain phases of a syndrome. Cysts and giant cell tumors in osteitis fibrosa can be easily discovered clinically because of the local bone enlargement. Occasionally the weak bone shell perforates and severe hemorrhages occur. Cysts of osteitis fibrosa are the result of organization of hemorrhages and are therefore later stages of giant cell tumors.

Single bone cysts usually occur in early life. Osteitis fibrosa generally is found between the ages of 40 and 45 and mostly in women. The diagnosis of a single giant cell tumor in adults therefore warrants a thorough examination of the entire skeleton and the metabolism. Local surgical treatment, i.e. scraping of cysts and giant cell tumors and the insertion of bone grafts will be of no avail if an adenoma of the parathyroid glands is present. Excision of the adenoma will eliminate the vicious circle which causes severe decalcification of the skeleton, and help in the treatment of nephrolithiasis, pyelitis and albuminuria. Muscular power will greatly improve. Cysts and giant cell tumors can be treated surgically after the parathyroid glands have been removed. In spite of the fact that the parathyroid plays a secondary part in osteitis fibrosa occasionally complete recovery has been observed after removal of the parathyroid glands.

2 Osteitis deformans (Paget). In Paget's disease a chronic nonspecific osteitis is found. There is a hereditary factor as well as a constitutional factor. There is no endocrine disturbance. The blood content of calcium and phosphorus is unchanged and may occasionally show a decrease of calcium and an increase of phosphorus. Parathyroid adenomas are absent. Occasionally there is parathyroid hyperplasia similar to that found in any other bone disease in which decalcification occurs. There is a serious inflammation of the bone marrow and a disturbance of the bone lamellae structure which is manifested by irregular apposition and destruction

of the bone. A mosaic type pattern with increased cement lines is noticeable, this is characteristic but definitely not specific of Paget's disease. The slow change in bone structure in Paget's disease leads to an increase in thickness of the bones. The bones are weak and spontaneous pathologic fractures occur. Roentgenograms of the entire skeleton are characteristic. Coxa vara, saber shaped tibia, and deformities of the radius are common. The full blown picture of Paget's disease is characterized by a large head thick bones and ape-like posture. Surgery is indicated in the case of compression of the spinal cord or of the spinal nerves within the foramina.

3. Renal osteitis fibrosa in adults. The differentiation of a renal form of osteitis fibrosa generalisata in adults in which the skeletal changes are associated with kidney changes is not justified. In 50 per cent of all cases of osteitis fibrosa in which there are changes of the mineral metabolism, the formation of cysts and brown tumors and damage of the kidneys are found. Uehlinger suggests the name renal osteopathy of adults for bone changes with kidney damage. Mandibular changes observed in experimental poisoning with platinum, gold, iron, or tin reach the jaw by way of the kidneys. Damage of the kidneys may cause decalcification of the skeleton. Hyperplasia of the parathyroid glands occurs secondarily.

Giant cell tumors and bone cysts occur without any other signs and are found in adults as well as children. Adults are more likely to have giant cell tumors and children more often cysts. The term "local osteitis fibrosa" is not good.

4. Bone cysts in infants. Bone cysts found in children and adolescents have no relation to Recklinghausen's disease. No known case of a single bone cyst followed up for 30 years later developed into Recklinghausen's disease. Hemorrhages within the bone marrow may be the cause of bone cysts or the cysts may be due to mesenchymal tumors (hamartia). Giant cell tumors are true tumors which may precede the bone cysts. The juvenile bone cyst is usually discovered after it has reached a considerable size or has caused a spontaneous fracture. The bone cyst originates either by hamartia of tissue composed of fibrocytes or from bone marrow hemorrhage. The histological picture will vary according to the biopsy site and the etiology of the lesion. Juvenile bone cysts are located in tubular bones within the metaphysis and are found in children under 15 years of age. Bone cysts found in adults usually originate from giant cell tumors. The upper humerus, the femur and the tibia are more frequently affected than any other bones. The roentgenogram is that of a multilocular cyst and is well demarcated proximally and distally. The cortex is very thin. There is no periosteal reaction. There is no disturbance of mineral metabolism. There is never any evidence of hyperparathyroidism. A biopsy is not necessary. One is not unlikely to mistake a bone cyst for a sarcoma on x-ray examination or on the basis of a clinical examination.

The treatment of osteitis fibrosa consists of the insertion of bone grafts. In cases of incomplete fracture, immobilization alone may lead to complete cure. At operation the juvenile cyst reveals a chocolate brown or serous colored fluid. A brown tumor type of tissue is found only in the walls of the cyst or giant cell tumor type tissue. The insertion of bone grafts is important because it takes a long time for big bone spaces to heal without the help of additional osteogenic tissue. Bone cysts of flat bones in children usually are composed of giant cell tumor tissue. Rarefaction in bone on roentgenograms may indicate a true cyst or a giant cell tumor. Experience has taught the author that large multilocular cyst formations in the long bones of children usually indicate juvenile cysts and that smaller multilocular cysts with thick partitions within the epiphyses in adults indicate giant cell tumors. Small cysts within the cortex in adults usually contain giant cell tumor tissue.

5. Polycystic localized osteitis fibrosa may affect one bone or an entire extremity. A similar picture is found in juvenile bone cysts. Histological examination reveals giant cell tumor tissue and cyst formation. There is no endocrine disturbance and there is no disturbance of mineral metabolism. The treatment is the same as for juvenile bone cysts.

6. Giant cell tumors. The syncytial fibroblastic giant cell tumor formation which is found reactively in osteitis fibrosa generalisata occasionally is observed separately and has to be considered as a true tumor. There is no disturbance of mineral metabolism. It seems unreasonable to believe that giant cell tumors in osteitis fibrosa generalisata are the result of bone marrow hemorrhages and to assume that giant cell tumors which occur independently are true tumors. Dense fibrous tissue within a scar may resemble a true fibroma. Hyperostoses may resemble true osteomas. The benign giant cell tumor usually occurs within the epiphyseal ends of the long bones in young adults. Giant cell tumors occur also in flat bones. The cortex becomes thin because of the expansive growth of the tumor and may occasionally stimulate growth by infiltration. Occasionally perforation of the periosteum is seen. In these cases differential diagnosis from osteogenic sarcoma is very difficult and the biopsy is the deciding factor. The treatment consists of curettage, implantation of bone grafts and fusion in cases in which joint destruction is present. Unfortunately there is a malignant variant of giant cell tumor which is a true sarcoma. Repeated incomplete excisions of the tumor, irradiation and postoperative infection may be the cause of malignant changes.

Small cystic foci are occasionally seen in the cortices of the long bones. The histological examination usually shows giant cell tissue and rarely cyst formation. These cysts are caused by endogenous or exogenous causes for example bacterial emboli.

7. Polyostotic osteitis fibrosa. This is an endocrine disturbance associated with changes in the bones. There is never a parathyroid adenoma.

present. A better term would be polyostotic fibrous dysplasia associated with pigmentation of the skin and endocrine dysfunction. The familiar occurrence, its appearance in young individuals and its unilateral occurrence points to a gene-associated condition. There is no metabolic disturbance. There is always precocious puberty.

8 Renal osteitis fibrosa in children. This condition is known as renal rickets and was formerly known as renal dwarfism. Renal rickets is a disease which occurs in early adolescence with retardation of growth, pallor, fatigue, polyuria, and polydipsia. The urine contains albumin and cylinders. There is hyperproteinemia and increased blood pressure. Fractures and bowing of the long bones are found. Occasionally the x ray examination reveals signs characteristic of rickets. Irregular epiphyseal lines, cup formation, osteoporosis, and infarctions are present. Originally interstitial nephritis was considered to be the cause of renal rickets. More recently kidney atrophy and pyelonephritis were considered the etiologic factors involved. In many cases an infection is implanted in a congenital malformation of the kidneys.

The bony changes associated with chronic insufficiency of the kidney usually cause parathyroid hyperplasia, which is also found in rickets. Eger caused kidney damage in rats with uranium nitrate, which usually was followed by hyperplasia of the parathyroid gland and osteitis fibrosa changes in bones. The changes in the bones are caused by way of the parathyroid glands and are similar to the ones observed in renal rickets. It was found that the bone condition was greatly improved by the administration of vitamin D and AT 10. Vitamin D has no influence whatsoever on osteitis fibrosa. Renal rickets is a disease which sometimes resembles osteitis fibrosa and sometimes true rickets.

Osteitis fibrosa is characterized by (a) a mineral metabolism disturbance with a negative calcium balance and a hypophosphatemia (organically) (b) permanent changes in the bones and parathyroid adenoma (morphologically) and (c) muscle weakness, deformities due to bone cysts and bone tumors, and secondary damage to the kidneys (clinically). The cause of osteitis fibrosa probably is a complex disturbance of the endocrine glands with particular emphasis on the parathyroids. A vicious circle is set up with an increased amount of decalcification of the skeleton. This sets up another vicious circle because, as the result of the damage to the kidneys, "acidosis" follows and this in itself again causes decalcification of the skeleton. In rickets the following symptoms are found (a) organically disturbance of the mineral metabolism, especially lowering of the phosphorus blood levels with negative phosphorus balance, (b) morphologically: a decrease in calcification within the zone of temporary calcification at the epiphyses, increased formation and noncalcified osteoid in the same area, (c) clinically softening of the bones, especially of the calvarium and growth disturbance of the epiphyses with enlargement and bowing of the

bones. In addition there is disturbance of the tooth enamel. The calcium and phosphorus blood levels are important as well as the calcium-phosphorus ratio. Rickets occur at a calcium-phosphorus ratio of at least 4 to 1. The excess calcium salts can be excreted only with the help of phosphorus, with the result of a decrease in the phosphate salts. The phosphate concentration in the serum drops below the level necessary for ossification. Vitamin D medication not only improves the intestinal phosphorus absorption but also improves the utilization and retention of phosphorus in the bones. In infantile rickets hypophosphatemia is discovered prior to the bony changes. Decalcification of the skeleton goes hand in hand with changes in the mineral metabolism. It may be due to (1) dietary calcium deficiency (2) deficiency of phosphorus, or a discrepancy between the calcium and phosphorus levels, (3) lack of vitamin D (4) lack of ultra violet rays, (5) lack of vitamin C (6) disturbance of the endocrine glands and (7) a general disturbance of the metabolism resulting in acidosis. There is a definite relation between vitamin D and the parathyroid glands, calcium and phosphorus, metabolism, vitamin D and fat metabolism and between vitamin D and lack of ultra violet rays, and between acidosis and parathyroid activity. Osteitis fibrosa generalisata cannot be considered exclusively as a bone disease. The calcium-phosphorus metabolism is disturbed and since the skeleton is the main source of these minerals it shows marked changes in its morphology. There is a common central origin for both osteitis fibrosa and diabetes. Both appear predominantly around the time of the menopause at the time when there is a re-arrangement of the endocrine glands. Women are predominantly affected, and pregnancies prior to the onset of the symptom influence the course of the disease.

Osteopathies in which decalcification of the skeleton occurs as evidenced by osteoporosis may lead to pathologic fractures. The more severe decalcifications lead to malacias which cause bowing of the bones.

GEORGE I. REISS, M.D.

Ischemic Contracture, Local, in the Hand. STERLING BUCKELL, EDWARD W. DOWDNEY and RAYMOND M. CURTIS. *Plast. Reconstr. Surg.* 948, 3: 424.

Ischemic contracture of the hand is a disabling fibrous degeneration of the intrinsic muscles of the hand which can be improved by surgery. It is caused by a tight plaster cast, injury to the brachial plexus, trauma to the two main arteries of the arm, or any other type of constricting bandage causing decreased circulation in the hand.

The hand assumes the position of a claw and there is adduction of the thumb. The fingers are flexed at the proximal joints and extended at the distal joints and there is flexion of the metacarpophalangeal joints. This position is similar to the one seen in combined paralysis of the median and ulnar nerves. The changes in the hand are permanent. The pulse is present except when the main artery is interrupted.

The tensesness of the interossei is demonstrated by failure of active or passive flexion of the distal two joints of the finger on hyperextension of the metacarpophalangeal joints. There is little or no active motion of the thumb.

Incision of the fascial covering of each intrinsic muscle is beneficial in early cases. In older cases stripping of the interossei and allowing them to retract distally is of benefit only if there is still some activity in the muscle. In cases in which only fibrosis is discovered complete tenotomy is done and a sublimis tendon is transferred at a later date.

The thumb is mobilized by bisecting the cleft and by holding it in that position by a bone block or by a pulley transfer operation for opposition. The defect in the skin is closed with a skin flap.

GEORGE I. REES, M.D.

Early Coxa Plana. Age Studies. *FOLKE STRÅM. Ada. erikop scand., 1948, 17, 180.*

The author's study was undertaken to determine the age of patients at the onset of coxa plana, and whether an earlier age of onset is associated with more rapid healing. The healing time in coxa plana is compared with that of aseptic necrosis of the femoral head following closed reduction of congenitally dislocated hips.

In order to estimate the duration of the disease prior to the initial roentgenogram serial films of 103 cases were studied. This information, together with opinions expressed in the literature helped to establish the following criteria.

Cases presenting early changes accompanied by more or less pronounced sclerosis of the caput epiphysae were considered as having existed for at least 3 months. If conspicuous fragmentation was visualized its duration was believed to have been 9 months and if the healing process was evident on first examination it was considered that the pathological process had existed at least 18 months prior to examination. A more accurate evaluation of the ages of the disease was deemed impossible.

The average age of patients at the first examination was 7.7 years. The highest age was 13 years and 1 month, the lowest, 2 years and 5 months. The lowest estimated age at onset of the disease was 2 years and 2 months and the highest age at onset was 13 years and 1 month in a patient who was under observation for the opposite earlier affected hip. The average estimated age of patients at onset was 6.6 years. Usually the condition was observed about 1 year prior to the first visit to the diagnosing surgeon so that the disease had progressed markedly before treatment was initiated.

Beginning resorption of earlier affected parts was considered the first sign of healing and on this basis the average healing time was 16 months. The shortest period required for healing was 7 months and the longest at least 34 months. Healing was a little slower in the older age groups.

Of the small total of 23 cases of coxa plana which were followed up at regular intervals (from the be-

ginning of the condition until restitution with substantially normal bone structure in the caput epiphysae), the average period of evolution was 36.4 months—the shortest, 21 months and the longest 54 months. The average healing time in patients under 7 years of age was 35.0 months and in patients over 7 years of age 38.6 months.

In 22 cases of epiphysitis following reposition of a congenital hip dislocation the average time of onset was 3.7 months following reduction, the shortest interval was 2 months and the longest, 7 months. The average age of these patients was 2.7 years, the youngest being 1 year old and the oldest 7 years old at the onset of the epiphysitis. In 16 cases studied sufficiently to determine the onset of healing 8.4 months was the average time, 5 months was the shortest, and 12 months the longest time. This may be compared with an average of 16 to 18 months in coxa plana. Only 6 cases were followed long enough to determine the time required for complete healing after reposition—an average period of somewhat less than 2 years.

The author's analysis seems to bear out the generally assumed fact that aseptic necrosis of the femoral head in childhood heals in the shortest time in the youngest patients.

KENNETH H. SPONDEL, M.D.

Significant Anatomic Relations in the Syndrome of the Scalene Muscles. *HOMER D. KIRKIN and ADRIAN F. REED. Ann. Surg., 1948, 127, 1182.*

Bilateral dissections of the area in question were done on 56 cadavers in an effort to discover significant anatomic relations. Particular attention was directed toward the modifications in structure and anatomic relations of the scalene muscles, the components of the brachial plexus and the adjacent vessels.

In all cases most of the fibers of the scalenus anticus muscle arose from the anterior or inferior surface of the anterior tubercles of the cervical transverse processes from the third to the sixth cervical vertebrae inclusive. These fibers even if in marked spasm are not strategically located to compress adjacent roots of the brachial plexus. The only possible way for this portion of the muscle to contribute to the syndrome is by elevation of the rib to which it is inserted with consequent trauma to the lower trunk of the brachial plexus. It is possible that such elevation of the first thoracic rib might, in some cases, constrict the lumen of the subclavian artery.

The location and size of the scalenus medius muscle are not suitable for the muscle to assist greatly in elevating the first rib. The effectiveness with which the scalenus medius muscle functions in raising the rib is to a large extent dependent on the size of the muscle and the distance of its insertion from the point about which the rib rotates as it is raised. The distance between the point of emergence of the first thoracic nerve from the intervertebral foramen and the point at which it crosses the scalenus medius muscle is an index of the amount of traction which

may be exerted upon the nerve with contraction of the muscle. This distance was established approximately by measuring the interval between the head of the second rib and the anterior point of attachment of the scalenus medius to the first rib. I practically all dissections the lower trunk of the brachial plexus rested on the inferior portion of the anterolateral margin of the scalenus medius muscle as it descended into the upper extremity regardless of the relation between the attachments to the first rib of the scalenus anticus and medius. The anterolateral border of the spastically contracted scalenus medius muscle may act as a sharp ridge over which the component roots of the brachial plexus, especially the seventh and eighth cervical and the first thoracic roots, are drawn by the normal activity of the upper extremity.

The author concludes that it is impossible for the main body of the scalenus anticus muscle that is, that portion arising from the anterior surfaces of the cervical transverse processes, to compress directly the components of the brachial plexus. This part of the muscle is important in the syndrome only through its activity in elevating the first rib and in serving as a rigid structure against which the displaced subclavian artery may be compressed. However direct compression of the fifth sixth and seventh cervical nerves especially of the latter two may result from contraction of the bundles of muscle fibers which arise from the inferior and posterior aspects of the cervical transverse processes and join the main body of the scalenus anticus muscle.

There are several factors which are of importance in the production of this syndrome of the scalenus muscles, namely (1) elevation of the first rib by the activity of the scalenus anticus and medius muscles aided by the scalenus minimus muscle when the latter is present, with irritation to the lower components of the brachial plexus (2) contraction of the "posterior" components of the scalenus anticus muscle with compression of the immediately adjacent nerve root or the subclavian artery and (3) traction of the components of the brachial plexus especially the seventh and eighth cervical and first thoracic nerves, across the anterolateral margin of a spastic scalenus medius muscle.

The vertebrocostal ligament occupied the characteristic position of the scalenus minimus muscle bilaterally in 10.7 per cent and unilaterally in 3.5 per cent of the dissections. The attachments were found to be similar. This ligament becomes relaxed as the rib is elevated. The situation in which it would carry out such a function most efficiently is one in which the scalenus medius contracts sufficiently to displace the first thoracic and eighth cervical nerves but not enough to elevate the first rib.

The surgical treatment of the scalenus muscles should include resection of the major portion of the scalenus anticus and of the scalenus minimus or vertebrocostal ligament when either of the latter is present. In addition, if it is apparent that the lower trunk of the brachial plexus may be traumatized

by angulation across the anterolateral border of the scalenus medius as is suggested by the approximation of its insertion to that of the scalenus anticus the portion of the scalenus medius immediately posterior to the lower trunk of the plexus should be resected.

C. FRED GOFRIEDER, M.D.

Traumatic Necrosis of Prefibular Muscles. CARL PEARSON, RAYMOND D. ADAMS, and D. DENNY BROWN. *N. England J. M.* 1948, 239-242.

A 24 year old man who had emigrated from Greece less than a year prior to this report was employed as a bus boy, and his duties required a considerable amount of walking. After competing with two companions in broad jumping on a cement pavement, he experienced sharp pains in the anterior aspect of both lower legs.

Examination revealed a foot drop bilaterally and complete paralysis of the anterior tibial muscles, the extensor digitorum longus and the extensor hallucis longus muscles. The neurologic examination was negative. The man's temperature was 100.8 degrees, and albuminuria and mild leucocytosis was found. Tests for parasites and venereal diseases and x-ray examinations were negative.

On the third hospital day the patient appeared ill, and his temperature rose to 102.4 degrees. The patient was given penicillin intramuscularly. On the fourteenth hospital day he was feeling quite well but the foot drop and the paralysis of the muscles persisted. A biopsy of the anterior tibial muscle revealed that parts of the skeletal muscles were replaced by fibrous tissue. In some instances different stages of degeneration were observed. There was some increase of the interstitial fibrous connective tissue. There were many macrophages containing hemosiderin and fewer lymphocytes. There was thickening of the walls of the small arteries.

The patient was seen 5 months after the illness. Bilateral foot drop and paralysis of the anterior tibial muscles were still present. A possible relation of this condition to the so-called "shin splints" was considered. It is believed that the violent contraction of the anterior tibial muscles may have caused rupture of the muscle fibers and hemorrhage, and expansion of the muscle fibers within the tight fascial compartment may be responsible for the ischemia and degenerative changes.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Open Reduction for Slipping of the Upper Femoral Epiphysis. STEN FARRER. *Acta orthop scand.* 1948, 17-18p.

At the Karolinska Institute the author has under his care a series of 70 patients, in the early "pre-slipping" state of slipping of the upper femoral epiphysis, who have been treated by the blind method of Smith-Petersen nailing. This method of

treatment is used in those cases in which at least two-thirds of the slipping surfaces are in contact. He believes that the so-called closed reduction is largely an illusion, and the trauma so great that necrosis often results. He does not find traction as satisfactory as the nailing procedure.

Greater slipping occurring at the time of the initial examination is a more serious problem. Since 1944, the author has performed open reduction and nail fixation in 13 severe cases. In the earliest case there was complete acute displacement, which prompted this manner of treatment. One other patient with acute displacement was so treated. Subsequently 11 patients in whom the slipping occurred more slowly have been subjected to open reduction by means of a wedge osteotomy and the nailing procedure. The wedge is taken from the femoral neck adjacent to the epiphyseal line and the base of the wedge is faced ventrally and cranially. The dimensions of the wedge are determined by the degree of slipping and on its estimated duration. In early cases satisfactory reduction is obtained with smaller wedges.

The author wishes to achieve reduction without placing a stretch on the posterior soft tissue connections; therefore the wedge should be large enough to avoid stretching the posterior structures which carry the circulation to the head. He believes that this may explain why no head necrosis has occurred in this series of 11 cases. He further advises that the nail be directed posteriorly into the head in order to rotate it into the osteotomy line. Anterior position of the nail might further displace the head. Illustrations demonstrate the author's insistence on good lateral roentgenograms of the hip.

In 12 of the 13 severe cases the preliminary results have been judged. In 10 of the patients the results are objectively and subjectively very good and necrosis has not been observed up to the present time. In the eleventh case total necrosis was present before operation. In the twelfth case reduction was not satisfactory, this case showed partial necrosis at one time which rapidly resolved. The final case was one in which a slight infection occurred postoperatively, with some decalcification and narrowing of the joint space. The patient considers himself symptom-free but the future of the joint is doubtful.

The author believes that open reduction should be unnecessary in cases in which the diagnosis is made very early. From a technical point of view it is rather difficult, and the necessary condition for a good functional result is an exact reduction. With regard to the late results nothing can be said at this time.

Preoperatively the radiologic examination revealed slight narrowing of the joint space and at operation a softening of the cartilage was seen. A normal hip cannot be expected but the results must be evaluated by comparison with the condition of these patients without operation.

KENNETH H. SPONSLER, M.D.

Hamstring Tendon Transplantation for the Relief of Quadriceps Femoris Paralysis in Residual Poliomyelitis. A Follow Up Study of 134 Cases. J. R. SCHWARTZMAN and C. H. CREGO, JR. *J. Bone Surg.* 1948, 30-A 541

A total of 134 hamstring tendon transplantations for the relief of residual quadriceps paralysis in poliomyelitis has been observed including the original 63 cases reported by Crego and Fischer in 1937 in which the biceps femoris tendon alone had been transplanted to the patella. The follow-up periods ranged from 1 to 22 years. An analysis of the end results is presented and the principles, technique and conclusions in the original report are modified.

The results of the present analysis of cases are reported according to the following grouping: (1) transplantation of the biceps femoris alone to the patella; (2) transplantation of the biceps femoris and semitendinosus to the patella; and (3) transplantation of the semitendinosus alone to the patella.

An excellent method of evaluating the end results is described in the article.

From the standpoint of muscle power it is believed that the patients eligible for reconstructive surgery are those who have sufficient residual muscle power to warrant the reasonable expectation that apparatus can be discarded postoperatively. Active co-operation on the part of the patient is essential for postoperative rehabilitation and mental inability to co-operate is therefore a contraindication to reconstructive surgery.

Fixed deformities such as flexion of the hip, flexion of the knee and equinus of the foot, must be corrected before hamstring transplantations.

The operative technique remains the same as that originally described by Crego and Fischer for transplantation of the biceps femoris alone. In transplantation of the biceps and semitendinosus simultaneously the additional procedure of detaching the semitendinosus from its insertion in the upper portion of the tibia and drawing the tendon out through an incision over the musculotendinous juncture of the semitendinosus on the posteromedial aspect of the thigh is carried out. The fascia of the muscle is split longitudinally toward its origin sufficiently to allow the tendon to be threaded forward through an oblique subcutaneous tunnel toward the patella. Care must be taken that the tunnel is directed in a gradually oblique direction toward the patella, and that the fascia of the muscle is opened sufficiently to allow a gradual oblique pull of the muscle on the patella, since a sharp angular pathway to the patella decreases the efficiency of the muscle pull. This principle is brought out in detail in the technique of biceps transplantation. The semitendinosus tendon is then anchored into the body of the patella.

It is important to stress the necessity for care in dissecting the biceps and semitendinosus tendons from their insertions, since it is essential to preserve the tibial and fibular collateral ligaments intact.

Upon completion of the operation the extremity is immobilized in plaster of paris from the groin to the

toes, with the knee in from 175 to 180 degrees of extension. Physiotherapy is begun between the third and fourth weeks after operation. Complete removal of plaster during the eighth week is followed by active flexion of the knee against gravity. As soon as sufficient power has been obtained to stabilize the knee in extension, the patient becomes ambulatory without braces. It is now believed that postoperative braces may favor rather than prevent the development of recurvatum.

Factors causing failure of the operative procedures were (1) lateral displacement of the patella (2) recurvatum (3) total failure of the transplant to function and (4) instability of the knee. The authors believe that the development of recurvatum will be kept to a minimum if (1) fair or better power is present in the gastrocnemius (2) postoperative hyperextension of the knee in plaster is avoided (3) equinus deformity is corrected before weight bearing is begun postoperatively (4) postoperative braces which will throw the knee into recurvatum are avoided and (5) diligent postoperative physical therapy to promote active flexion of the knee is carried out.

The following conclusions are given () hamstring substitution for residual paralysis of the quadriceps muscles in poliomyelitis is a highly satisfactory operative procedure (2) simultaneous transplantation of the biceps femoris and semitendinosus to the patella is a much more satisfactory procedure and produces far better results than transplantation of the biceps alone

RUDOLPH S. KATZ, M.D.

Intraepiphyseal Arthrodesis in the Treatment of Tuberculosis of the Knee in Children (La résection intra-épiphyse dans le traitement de la tumeur blanche du genou chez l'enfant) PIERRE GROUTZ. *Lille chir.* 1947 1: 289.

Intraepiphyseal arthrodesis was first used by Syme and by Olier and was later discarded because of high mortality and frequent recurrences. In later years, and especially after 1925, conservative treatment of tuberculosis was adopted and "nonintervention therapy" was favored. The author favored resection of bone and arthrodesis as the operative treatment of choice.

Calve and Galland reported the results of conservative treatment of tuberculosis of the knee cure with resitutio ad integrum in 25 per cent of the cases, cure with ankylosis in 10 per cent, and cure with partial ankylosis and a tendency to flexion deformities in 65 per cent. Sorrel reported results on 271 cases: cure in 43 per cent of children ankylosis with good position in 30 per cent, and poor results with incomplete ankylosis in 30 per cent. It is generally agreed that "cure" does not exclude a recurrence in from 3 to 5 years.

A number of intra-articular juxta-articular and para-articular ankylosis of the knee and their disadvantages are enumerated. It is pointed out that in most arthrodeses all or part of the cartilage is left undisturbed.

Best results were obtained in children between the ages of 12 and 13 years. Operation is not done until 8 months have elapsed since the onset of the infection. The temperature must be normal for at least 2 months. Good results were observed in old cases in which healing would not occur and in cases in which ankylosis did not occur because of interposed cartilage also in cases of ankylosis in poor position.

The operation is contraindicated if there are acut draining sinuses, in generalized infection, in cases with multiple tuberculous lesions, sinuses, or early ankylosis and in cases in which the diagnosis is not definitely established.

The technique is as follows: under general anesthesia and with the use of a tourniquet around the thigh a large "U" incision is made about the patella and is carried down through the aponeurosis. The patellar tendon is sectioned. The knee is slowly flexed which severs all fibrous bands. After freshening up of the condyles, the tibial plateau and the posterior aspect of the patella, the ends of the epiphyses are resected with correction of any existing deformity. Sequestra and necrosis of the synovial membrane are removed. The wound is closed and a cast is applied with the knee in slight flexion.

Forty children were operated on by intraepiphyseal arthrodesis. Two died because of shock (operation was performed without a tourniquet). In each of 38 patients a good ankylosis was found 3 or 4 months postoperatively. Three patients developed genu recurvatum. There was some slight growth disturbance following this procedure which probably would have occurred even if the operation had not been carried out.

GEORGE L. KIME, M.D.

Positive Pressure in Arthrodesis of the Knee Joint. J. C. CHARNLEY. *J. Bone Surg.* 1948, 30-B: 478.

The method of arthrodesis of the tuberculous knee joint, described by Key in 1935, was utilized by the author in 15 consecutive cases. Clinical union was detected at the first inspection in from 12 days to 6 weeks after operation. By this method the total period of disability was reduced to 3 months. In 6 cases the operation was performed for old tuberculous disease of the knee joint with fibrous ankylosis in bad position, and in 9 cases for osteoarthritis. Three mechanical factors which might be responsible for this very early clinical union were examined: compression is believed to be the main factor, although fixation is also important. The technique used in these cases is as follows:

Under a tourniquet the skin is incised in the midline, and the patella is excised. The knee is flexed, and the bone ends are sawn in such a way as to give flat surfaces of cancellous bone which when opposed, leave the limb almost but not quite straight. The bone surfaces are held together by an assistant and the edges of the skin wound are temporarily approximated by one or two volsella. This enables two parallel Stehmann nails to be passed, one through the upper end of the tibia and one through the lower end of the femur without tension on the skin sur-

Fig. 1

Fig. 1 (Charnley) Arrangement of nails and clamps on femur and tibia. Note the coaptation.

Fig. 2.

Fig. 2 Shows the "hairline" fit of the joint surfaces seen at operation.

rounding the nails when the wound is finally sutured. The nails are 4 mm. in diameter and 9 or 10 inches long. The projecting ends are connected by special screw clamps and the wing nuts are tightened until the nails bow under the compression force. In contrast to the postoperative technique utilized by Key in which the pins were incorporated in a plaster cast the author used a Thomas splint.

Arthrodesis of the knee joint by other methods may take an average time of 6 months, and there is an appreciable incidence of failure. The feature of this technique is the accuracy of timing which is possible. It is known precisely when bone union will occur. When compression is used in the manner described it may be predicted with certainty that the clamps can be removed after 4 weeks with the knee showing clinical union that union by bone will be present in eight weeks, as indicated by the absence of pain on straining the ankylosis and that the patient will be fit for re-employment by the end of the third month. Union takes place between two perfectly coapted surfaces of cancellous bone with intact circulation. Union of the arthrodesis is thus comparable to that of a fracture without displacement, under ideal conditions. Both the cut bone surfaces share actively in osteogenesis. By contrast, methods of arthrodesis which depend upon a bone graft seem illogical. Though it is customary to state that a bone graft can be used to combine the functions of internal fixation and osteogenic stimulation in actual fact a graft provides very imperfect fixation and cortical bone has less power of osteogenesis than the bones which it joins together.

The author indicates that bone grafts are capable of mechanical function in not less than 4 or 5 months. The graft is less osteogenic than the substance of the bones which form the joint and it provides inefficient internal fixation.

A theory is suggested that compression even in the presence of slight movement, acts by producing a fixed "hinge" without shearing movement at this point a bridge head of flexible osseous tissue is established in which ossification inevitably takes place despite a slight bending movement. A second theory is suggested that high compression forces stimulate early union by liberating bone salts at points of maximum pressure through the action of osteoclasts and that the local excess of bone salts is redeposited under cellular activity within a range of a few millimeters where there is no pressure.

C. FRED GORRINGER, M.D.

The Tendency Toward Conservatism in the Removal and Subsequent Reparative Surgery of Bone Tumors of the Articular Extremities at the Knee Joint (Indirizzo di chirurgia conservativa e riparatrice nei tumori ossei degli estremi articolari del ginocchio) G. GHERLINZONI. *Chir. org. movim.* 1948 32 189.

Thirteen bone tumors of the juxta-articular bone ends at the knee joint are reported. These new growths included a giant cell tumor which had recurred after surgical removal, a myeloblastoma or immature giant cell tumor as distinguished from the less malignant mature giant cell tumor of Scaglietti, a sarcomatous metaplasia of a myeloblastoma, 5 myeloplastic sarcomas, 2 osteogenic sarcomas and 3 chondrosarcomas.

The Putti Juvara operation was done in all of these patients. This consisted of the resection of the end of the affected bone followed by the turning upside down of a massive implant from the end of the apposed bone and intramedullary fixation in the usual manner. The other end of the implant was fixed to the surface of the parent bone with a circular ligature of catgut or of wire. The length of the

implant was kept down to between 15 and 18 cm even at the expense of shortening the extremity.

Consolidation of the implant was obtained in 8 of these cases following an average period of immobilization in plaster of 15 months. There was an average shortening of the limb of 3 cm. Pseudarthrosis developed in 3 instances. In 2 of these the faulty result was due to suppurative processes. In no case was the pseudarthrosis subjected to any further measures.

In 2 of the chondrosarcomas local recurrence developed and the limb was amputated. The patient with the sarcomatous metaplasia of the myeloblastoma and the 2 patients with osteogenic sarcoma, which was frankly malignant, have survived the operation, the one for 15 years and the other for 3 years. The patients with the immature giant cell tumor (myeloblastoma) the chondrosarcoma and the myeloplastic sarcoma died of visceral metastases in from 3 to 4 years following the operation.

The author believes that the results procured in this series of cases justify the present tendency toward conservatism in the surgical treatment of these conditions.

JOHN W BRENNAN, M.D.

Arthrodesis of the Ankle Joint. J. CRAWFORD ADAMS. *J Bone Surg* 1943, 30-B 506.

During the last 4 years, the technique of transfibular arthrodesis has been performed in 30 cases at a London Hospital. The author presents a case report, accompanied by 4 illustrations depicting the operative technique most adequately. The author's method of operation is as follows:

A 5 inch incision is made over the lower end of the fibula and the fibula is exposed subperiosteally. It is divided 3 to 4 inches from its lower end, removed from its bed, and prepared for an onlay graft by splitting off its entire inner cortex. The lower end of the tibial (lateral) bed is prepared by removing all soft tissues commensurate with the site of the onlay. The ankle joint is fully exposed. All available interarticular cartilage is removed until the foot rests in the optimal plantigrade position. The fibular graft is immobilized by three long transcortical screws, one of which grips the astragalus. The wound is closed. A plaster of paris cast is applied. Weight-bearing is encouraged after 3 weeks.

Because of its simplicity—adequate exposure, close contact of the onlay graft from the tibia clear across the joint and onto the astragalus—the operation is conducive to a formidable arthrodesis of the ankle joint. As an alternative procedure the author suggests the insertion of a three-flange nail from the os calcis into the shaft of the tibia.

SAMUEL L. GOVERMALL, M.D.

The Surgical Treatment of Hallux Valgus (Il trattamento chirurgico dell'alluce valgo). D. LOCRONCINO. *Chir org movim* 1943, 32 8.

Sixty patients with hallux valgus were operated upon by various methods. In fact, it is considered that no one operation can be set up as a standard every

patient must be operated upon by a technique which is suitable to the particular conditions found. At the Rizzoli Institute in Bologna, Italy, where this material was collected, the operative correction by only those methods which involve the soft tissues have been largely abandoned and these techniques have been relegated to the position of occasional accompaniments to the skeletal procedures. This tendency may arise in part from the fact that the Rizzoli Institute tends to receive the more severe types of deformity, so that only the more radical procedures on the bones and joints affected would seem to offer assurance against recurrence.

In 16 patients the bony and articular changes were so severe that only an attempt at arthrodesis seemed indicated; however, this procedure should always be regarded as an ultimate refuge. In 4 instances the basal phalangeal bone was excised after the method of Alsborg and the results were on the whole, satisfactory, however the author does not like to sacrifice this bone since its joint surfaces are usually intact and the method does not correct the spread of the first metatarsal which is the basis of the entire deformity.

On the whole the operation most commonly done in the moderately advanced conditions has been some form of osteotomy on the first metatarsal bone. In fact the author has himself developed an operative technique which he has not seen previously described and therefore describes it in considerable detail. His operation consists essentially in the usual approach for a cuneiform osteotomy of the head of the first metatarsal bone; however, when this has been accomplished a second incision is made over the proximal end of the first metatarsal and this bone is again osteotomized, this time transversely. The cuneiform fragment is then implanted base side out into the new osteotomy tract, so as to throw the splayed first metatarsal toward the second metatarsal, from which position it has gradually diverged. Results from this operation in this type of case have been splendid, and photographs show the excellent cosmetic result procured. Of course, other procedures such as reshaping of the joint surface of the first metatarsal bone, capsuloplasty and even transplantation of the tendons, may be added.

A variation of the described operation has been worked out for cases in which the first metatarsal bone has become protruded forward which renders reduction of the deformity difficult. In this variant the cuneiform osteotomy is performed on the opposite surface of the first metatarsal, that is, the wedge of bone is removed from the lateral side of the bone down near its proximal end and thus the splayed distal end is more easily brought out to its normal position since the bone is shortened as well as abducted.

JOHN W BRENNAN, M.D.

Bone Lengthening. F. G. ALLAN. *J Bone Surg* 1943, 30-B 490.

Codivilla described the first bone lengthening operation in 1905. In 1913 Magnusson described his

experimental work on dogs and reported his performance of 14 such operations. Too rapid distraction on the Hawley table resulted in shock and death of one of the patients.

Abbott in 1927 described his own method as follows: osteotomy counter traction maintained by Steinmann pins above and below osteotomy tenotomy of tendo achillis insertion of drill pins circular division of the periosteum and deep fascia and the application of distraction apparatus.

Many modifications have since been advocated. Of particular interest, however are the contraindications issued therefrom. They are (1) loose control of hip and knee joints requiring permanent fixation (2) age (only adolescents and young adults are suitable patients), (3) lengthening greater than 3 inches, (4) recent joint or bone infection (5) very tall patients—shortening of long leg preferred.

The technique of lengthening of the tibia is that of an oblique osteotomy without circular stripping of the periosteum or fascia, and transverse osteotomy of the fibula at the same level as of the tibia. Two wires above and below the osteotomy are inserted in the tibia for the purpose of distraction the latter are tied to Kirschner stirrups which in turn are incorporated in the leg cast. Distraction is increased one-sixteenth of an inch a day until the desired length is achieved. Shock with undue pain is attributable to too rapid distraction with harmful tension on nerves muscles blood vessels and fascia or pressure on the skin overlying bony prominences.

Lengthening of the femur presents greater technical difficulty. Stiffness of the knee joint is a frequent concomitant. The author presents a report of 40 operations for lengthening the shaft of the femur in which he obtained an average lengthening of 1 3/4 inches with three failures.

Forty seven other operations were performed on the tibia and fibula in which an average lengthening of 2 1/4 inches was obtained with only one failure.

The average postoperative weight-bearing time was 5 months for the femur and 6 1/2 months for the tibia. Four and one third inches was the greatest lengthening achieved by this method. The reaction of bone to the operation was that of delayed union. All bones ultimately recovered their normal radiographic appearances. In 2 cases both leg bones became grossly decalcified.

The reaction of muscle to leg lengthening is adverse to its nutritional integrity i.e. too rapid lengthening interferes with the blood supply hence muscle wasting is inevitable. The lower leg is particularly vulnerable.

The reaction of the blood vessels during the lengthening operation is relatively innocuous. Their inherent elasticity allows considerable elongation in this adolescent group of patients.

The most vulnerable tissue reaction to leg lengthening is discernible in the nerves. Rapid sustained stretching is invariably associated with transient paralysis of the medial or lateral popliteal nerve. In the author's series the transient paresis of the

external or internal popliteal nerve was encountered 19 times or in about 22 per cent of the patients.

Joint stiffness in a mild form has been observed by the author.

In conclusion the author states that lengthening of 2 inches in the femur and 3 inches in the tibia can be achieved with relative impunity. Longer lengthening is obtainable with a high risk of transient paresis of the common peroneal nerve. Lengthening of the tibia is more feasible than lengthening of the femur. During traction lateral rigidity of the bony fragments is of paramount importance. In the opinion of the author osteotomy is best accomplished by closely spaced drill holes.

SAMUEL L. GOVERMAN, M.D.

FRACTURES AND DISLOCATIONS

Statistical Considerations of 337 Shoulder Dislocations, Including Posterior Luxations and Nerve Complications (Consideraciones estadísticas sobre 337 luxaciones del hombro. Las luxaciones posteriores y las complicaciones nerviosas). JOSE MANUEL DEL SEL. *Rev. ortop. traumat.* B. Añ. 1948 17: 202.

This article is an analysis of 337 shoulder dislocations attended at the orthopedic department of the Manchester Royal Infirmary. Of the dislocations reported 8 per cent were of the recurrent type, 19 per cent had associated bone lesions, 18 per cent were posteriorly directed, 56 per cent sustained nerve complications and 0.29 per cent disclosed some form of vascular injury. One of every 30 patients with dislocation developed deltoid paralysis. The frequency was approximately equal in both sexes, but showed a tendency to increase with age.

A plea is made for more thorough investigation of the entire shoulder musculature and meticulous testing of the nerves along with their dermatome and cutaneous distributions. It is believed that this alone will obviate any irreparable loss from atrophy or paralysis.

STEPHEN A. ZIEMAN, M.D.

Fracture Subluxations of the Shoulder. T. J. FAIRBANK. *J. Bone Surg.*, 1948 30-B: 454.

Among 115 cases of fracture of the upper end of the humerus 12 patients were found to have a downward subluxation of the shoulder joint. Of these 11 patients had fractures of the humeral neck (7 of the abduction type and 4 of the adduction type) and the twelfth patient had a dislocation with fracture of the greater tuberosity. The ages of the patients varied from 24 to 82 years. In 6 cases subluxation was present when the patients were first seen; in the other 6 subluxation appeared several days or weeks later. This subluxation may have been due to the violence of the injury to a weakness of the muscles which retain the humeral head in the glenoid or to loss of tone in the longitudinal muscles of the scapula. Experimental investigations were carried out on normal shoulders and dissections and roentgenographic examinations were made in the postmortem room.

It was further shown that

1. All structures running down the arm from the shoulder including the vessels and the nerves, play some part in maintaining the stability of the joint.

2. If the whole rotator cuff is divided, the force necessary to sublaxate the joint is only slightly diminished.

3. If all of the structures except the supraspinatus are divided the force necessary to produce sublaxation is very small.

4. The glenoid is too thin and pliable to have much of a stabilizing effect.

Experimental effusions into the joint cavity with air and water did not alter the stability of the joint significantly and it was found impossible to maintain any great tension because of the leakage under the subscapularis and down the long head of the biceps. A triangular sling for supporting the elbow prevents sublaxation without interference with the fracture. With the aid of physical therapy muscle tone rapidly improves and recurrence is prevented. In cases in which a triangular sling is insufficient it may be necessary to place the arm in abduction and forward flexion by means of a plaster spica.

RICHARD J. BENNETT, J. M. D.

Fracture of Hip. R. H. FREYER and M. D. LEVY
J Am M Ass 1948, 37: 90

To determine the incidence and type of medical complications in patients with fracture of the hip, a survey of such patients treated at the Hospital for Special Surgery, New York, was made for the 10 years ending December 1946.

Seventy-two per cent of the patients were women mostly between 70 and 80 years of age. Significant postmenopausal osteoporosis and obesity were encountered and considered important etiological factors. Twenty-nine patients, or 17 per cent, had significant complications: there was pneumonia in 7 cases with 6 deaths and pulmonary infarction in 4 patients with 2 deaths.

Pre-existing diabetes, arteriosclerosis or hypertension did not endanger the patients per se but would have complicated any superimposed infection or vascular accident. The over-all mortality rate was 7.2 per cent, with most of the deaths occurring in women and in the older patients who were confined to bed.

Prevention of obesity would certainly lower the incidence of hip fracture and weight reduction should be prophylactically undertaken in all obese older persons. A curtailed caloric intake may be started as soon as the treatment of the fracture is begun. A daily intake of 800-calories is adequate for the bedridden patient and should include from 60 to 80 gm. of protein and plenty of low carbohydrate vegetable fiber.

The osteoporosis in this group of patients is not a disturbance of the calcium and phosphorus metabolism but is due to the insufficient production of osteoid tissue. Prophylactic estrogen or androgen therapy according to the plan of Albright is sug-

gested for persons whose osteoporosis is appreciable. Prolonged bed rest is contraindicated.

Pneumonia killed 6 of 7 patients with this complication in this series but antibiotics were not available in most cases. The second major complication phlebotrombosis was more frequent in bed patients than in the postsurgical patients. Anticoagulants were not employed in this group and might have favorably influenced the outcome.

Immediate care with regard to optimum nutrition, by parenteral administration if necessary and vigilance against the onset of complications to afford early definitive treatment are the major needs in providing adequate medical care for these patients.

FRANCIS E. BENDISCH, M. D.

Results of Treatment of Fractures of the Hip. H. B. BORD and I. L. GEORGE. *J Am M Ass* 1949, 37: 90.

Fractures about the hip joint occur in 80 per cent of patients more than 60 years of age and chiefly in women (from 80 to 85%). Trochanteric fractures rarely end in nonunion for the blood supply to both fragments is adequate and much of the bone involved is cancellous. Conversely fractures of the femoral neck often cause loss of the blood supply to the proximal fragment and the area does not produce callus in any appreciable amount.

In trochanteric fractures the authors' mortality was 13 per cent, probably because of the greater trauma involved in the fracture and in its surgical reduction. However internal fixation with a Newfeld nail is their procedure of choice: this allows the patient early activity and reduces the mortality and the incidence of senile psychosis.

Statistics are offered on a series of 360 central fractures of the femoral neck of which 177 were followed up for more than a year. All deaths occurring within 4 weeks of operation were included in the mortality rate of 7 per cent. In the 100 patients under 70 years of age the mortality was 10 per cent but in older patients it rapidly rose to 42.0 per cent in the tenth decade.

Of the 177 patients followed up longer than a year 150 or 84.7 per cent obtained union, while 27 or 15.3 per cent suffered nonunion. In 13 of the 27 with nonunion reduction was inadequate but in the balance reduction was adequate and nailing was done. The shearing force in more vertical fracture lines is believed to have been adequately counteracted by good internal fixation.

Aseptic necrosis was seen in 32.6 per cent of the unions, and 59.3 per cent of the nonunions. Arthritic changes were markedly increased among the patients who were followed up for 2 years or longer. This included those in which definite collapse of the femoral head occurred in spite of union and disabled the patient as much or more than a nonunion would. Various operative procedures have been devised for the relief of this complication which now replaces nonunion as a major problem.

FRANCIS E. BENDISCH, M. D.

Fractures of the Acetabulum. MARSHALL R. URIST.
Ann. Surg., 1948, 127: 1150.

The author reports on 58 injuries of the hip joint which occurred in jeep accidents. There were 16 cases of fracture of the acetabulum, of which 5 were fractures of the rim of the acetabulum, 3 of the superior and 2 of the posterior rim. There were 8 cases of central fracture and 3 cases of comminuted fracture, which disorganized the entire joint cavity.

It is shown that the posterior rim of the acetabulum is necessary for stability while the superior shelving portion is vital for weight bearing but the anterior rim may be excised without seriously altering the function of the joint.

Seven fractures of the acetabulum from the fracture service of the Massachusetts General Hospital were studied. At the end of 2 years, 11 of the 14 military patients had no serious disability. Displaced fractures of the superoposterior rim of the acetabulum appeared to produce more symptoms and disability than fractures of the anterior rim and central fractures. One unreduced fracture of the posterior rim caused severe pain and some limitation of motion, and on the other hand one patient whose joint was accurately repaired at open operation had a normal hip. The 3 patients with extensive fractures of the acetabulum and destruction of the joint cavity had ankylosis and complete disability. An open operation through an anterior iliofemoral approach is practicable in very severe cases.

RICHARD J. BENNETT JR., M.D.

Fractures of the Ankle: Analytic Historical Survey as the Basis of New Experimental, Roentgenologic, and Clinical Investigations. N. LAVER.
Arch. Surg. 1948, 56: 259.

This is a historical survey of ankle fractures stressing the mechanism of fracture, the pathologic anatomy, the characteristic roentgen picture and the mechanism of reduction—genetic reduction. The subject matter is divided into three chronological periods: the clinical period, experimental period and roentgenographic period.

Under the clinical period the author discusses the recognition and treatment of ankle fractures from Hippocrates (about 300 B. C.) to Alexis Boyer (1803). During this period it became increasingly obvious that the fibular fracture is a very frequent, perhaps constant, complication in luxations of the talocrural joint.

Under the experimental period the author discusses the experiments of G. Dupuytren, Charles Bell, John Howship, Astley Cooper, I. G. Maissonneuve, M. T. Boyer and others. The chief advancement during this period was recognition of the fact that luxation of the talocrural joint is not only always accompanied by fracture of the lateral malleolus or of the fibula, but also is frequently accompanied by fracture of the medial malleolus and by diastasis between the tibia and fibula, and that several widely different forms of fracture of the ankle exist which according to experimental surgical investigations

are produced by varying mechanisms. Research on fractures involving the ankle by experimental surgery and autopsy came to a complete standstill with the introduction of roentgenographic diagnosis.

During the roentgenographic period the correctness of the conception formed in the experimental period has been borne out and it has been shown that fractures of the dorsal tip of the tibia are much more frequent than had been suspected, also that anterolateral fracture of the tibia, and diastasis distally between the tibia and fibula are not at all rare. Attempts are made to develop and improve the methods of treatment gradually as knowledge and understanding of the various forms of fractures are increased, but in spite of the extensive application of roentgen examinations with a view to diagnosing the fractures of the ankle and exploring their nature the problem is far from having been solved.

From his survey the author concludes that (1) the exact genesis of most fractures of the ankle is still unknown, (2) the problem of the relationship between the marginal tibial fracture and the malleolar fractures and between the former and rupture or detachment of syndesmotic ligaments has not been solved, (3) a sure knowledge of rupture or detachment of the ligaments of the syndesmosis in the various types of ankle fractures has not been reached, (4) the criteria of rupture or detachment of syndesmotic ligaments are uncertain, (5) the classification of the malleolar fractures in the literature is almost chaotic and (6) no attempts have been made to reduce the malleolar fractures in conformity with their actual nature.

In another article the author will present his study of roentgenograms from 229 patients in whom it was shown that it is possible to determine the origin (genesis) of all fractures of the ankle, their pathologic anatomy and their genetic roentgen diagnosis and by this means it was ascertained that the types of fractures of the ankle produced by experimental surgery correspond with 99 per cent of the clinical fractures.

JOHN J. CRANLEY JR., M.D.

ORTHOPEDICS IN GENERAL

Pneumoarthrography of the Knee Joint with Particular Reference to the Semilunar Cartilages.
KJELD ANDERSEN. *Acta orthop. scand.*, 1948, Supp. 4.

In this monograph there is a comprehensive section on the history of arthrography and several good ones dealing with methods of joint injection, roentgenographic exposure and the pathological anatomy of torn semilunar cartilages.

The author gives an account of his experience with 149 patients who were examined by the method of Mohlmann and Madlener. 68 of these patients were submitted to operation. After correlating the arthrographic findings with what was seen at surgery he concludes: "It appears that not only all major changes—bucket handle fractures with dislocation of the torn part and partial longitudinal tears with dis-

location of the torn part were demonstrable with considerable accuracy but the minor changes total and partial longitudinal tears without dislocation could also be diagnosed in practically all cases.

H. KELLERMAN, M.D.

The Practical Importance of an Infrequently Occurring Anatomical Continuity between the Tibiofibular Articulation and the Knee Joint (*Importanza pratica di una non frequente continuità anatomica fra ginocchio articolazione tibio-peroneale*) *Pediatrics* sec. chir. 948, 53-56

Two patients were operated upon at the Centro Ortopedico e Mutilati di V. Putti in Bologna for apical osteomyelitis involving the leg previously amputated at the upper and lower thirds, respectively. Reamputation was performed in both cases.

In the first patient the fibula was sectioned very high and suppuration spread rapidly from the tibiofibular articulation to the knee joint. In the second patient postoperative recurrent hemorrhage occurred from ulceration of an artery several centimeters above the incision. It was therefore necessary to reopen the wound and subsequently to reamputate the thigh for an abscess at the head of the fibula.

In both of these instances the anomaly of anatomical continuity between the tibiofibular articulation and the knee joint was found which in the first patient developed into major clinical significance and in the second remained an incidental finding.

EDITH B. FARNSWORTH, M.D.

Remarks on the Prognosis of the Posttraumatic Dystrophy of the Extremities. *STRAK KROK. Acta orthop. scand.* 948, 7-53.

The author's article concerns 35 patients with posttraumatic dystrophy of the extremities, who were treated by sympathectomy. In 22 patients posttraumatic dystrophy posttraumatic osteoporosis, or hard edema characterized by pain, limited function, swelling, and joint and skin changes was observed. Of these 5 patients have recovered completely and permanently, 6 have a partial disability, and 11 will continue to be markedly disabled. Of the remaining 5 patients, with moderate dystrophy, 2 have made a complete recovery.

The author believes that treatment should be instituted early, and he stresses repeated sympathetic block. In the present series of patients sympathectomy failed, however these cases were very severe or were of long standing. Ten of the patients presented a "nervous constitution" prior to the occurrence of the accident which was followed by dystrophy.

DANIEL H. LEVINTHAL, M.D.

Chronic Lesions of the Vertebral Column and Accidents of Work (*Lesiones crónicas de la columna vertebral y accidentes del trabajo*) *TRONCOSO GERRERO W. Arch. Soc. cir. hisp.* Santiago 947, 7-652

The author reports on 2 cases in which his opinion was requested. In the first, a coal miner aged 61

was struck on the back by a mass of debris and suffered a fracture of the eleventh thoracic vertebra. Because of persistent pain and kyphosis, an Albee bone graft was inserted but had to be removed 3 months later on account of infection. Twenty-two months after the accident the patient was allowed a 7 per cent disability. The author found a chronic deforming spondylitis of the entire spine.

Spondylitis is due to a pathologic change of the intervertebral discs which because of constitutional factors or degenerative processes lose their elasticity and normal height as age increases. A single trauma never causes it, and it is practically a normal manifestation in workmen more than 50 years of age. In vertebral fracture with lesion of the disc, marginal osteophytes usually develop after 4 to 6 weeks, especially on the anterior aspect of the vertebra, and unite two neighboring vertebral bridges. These formations are always limited to two or three vertebrae and have nothing to do with spondylitis. A spondylitic spine is more fragile than normal because its resistance is decreased by osteoporosis and loss of elasticity of the discs. Its spondylitic marginal formations may fracture because occasionally they are so close together on account of the decrease in height of the discs, that they easily touch one another on forced flexion of the spine. Rest, massage, and gymnastics cure most cases by callus formation in 2 or 3 months but even if a pseudarthrosis forms healing should not take more than 6 months. Whatever disturbances are then left are due to the chronic deforming spondylitis. To accept or reject an aggravation of a spondylitis by an accident is always a difficult problem for the expert when there are no clear signs of injury. Even when it is certain that the pain and functional disturbances of the spine have appeared for the first time on the occasion of the accident, it is not possible to incriminate the latter for something that had to occur unavoidably in the natural course of the disease. Guegele has summarized the problem as follows: there is no traumatic spondylitis, whether localized or generalized deforming spondylitis is the expression of a disease of the discs and not a traumatic change; there is no aggravation of deforming spondylitis by a compensable accident nor by a vertebral fracture.

In the second case, a coal miner also aged 42 was struck to the ground by a falling mass of coal and was treated with a cast for fracture of the iliac crest and of the first and second lumbar vertebrae. The cast was removed in 4 months. At the end of one year he was allowed 50 per cent incapacity. The author examined him 13 months after the accident and found no trace of previous fracture but a congenital anomaly with six lumbar vertebrae, spondylolisthesis, lateral inclination of the last lumbar vertebra on the base of the sacrum, and scoliosis of small radius with deformation of the vertebral bodies and discs through adaptation which could occur only during growth.

Spondylolisthesis is caused by an anomaly of vertebral growth at the level of the arches. Once estab-

ished it results in severe disturbances of the lumbago type which usually appear about the age of 30 and increase with age and may be associated with disturbances of the sciatic type caudal symptoms (paresthesias paresis paralysis) stiffness of the lumbar spine inability to do hard work, and a swaying gait. All these disturbances may be minor slightly developed or very evident according to the degree of the disease. The patient is generally a constitutionally weak individual who should not earn his living by hard work like that of a coal miner. The present patient had paresthetic alterations in the lower extremity which were attributed to medullary involvement caused by the accident, but which were exclusively due to his vertebral anomaly that irritated the spinal nerve roots at their exits from the narrowed foramina.

RICHARD KEMMEL, M.D.

The Value of the Faradocutaneous Sign of Hyperalgesia about the Paravertebral Region (Valore semeiologico della iperalgesia farado-cutanea della regione paravertebrale) VINCENZO NERI. *Chir. org. movim.*, 1947 31 72

The author presents another diagnostic measure that is useful in differentiating spinal lesions. Faradic cutaneous stimulation eliciting hyperalgesia of the corresponding dermatome is employed. Direct manual pressure often gives a negative response and affords no clue as to the underlying pathologic change. The paravertebral area between the nape of the neck and the sacral groove is investigated. Like the rectus abdominis muscles, the erectae spinal muscles manifest metameric innervation by the posterior branches of the spinal nerves. Because of this type of innervation one can recognize

changes in response to the electric current limited to that section of muscle that is solely innervated by one posterior branch of the spinal nerve.

The cathode is placed in the paravertebral region and slowly moved down the length of the spinal cord i.e., the vertebral column from the nape of the neck to the sacral area. The potential or quantity of current does not provoke pain. The subjective reaction is one of formication. When the cathode is placed over certain areas which are insensible to pressure sensations pain is elicited. This pain however does not register in the galvanometer reading. The area in which pain is elicited follows the distribution of the nerve as manifested by metameric innervation.

The author refers to many cases in which the afore-mentioned test was of great value. In many cases the sensation felt by the patient resembled a sudden sharp bite. The zone of hyperalgesia was distinctly limited both superiorly and inferiorly. The dermatome, which was hyperalgesic, corresponded exactly to the specific spinal root. This sign was valuable in the differential diagnosis of lesions of the cauda equina from those of the conus.

The faradic cutaneous hyperesthesia is also of value in early diagnosis of herniation of intervertebral discs and Pott's disease. In cases of compression in which the lipiodol does not reveal changes in the spinal canal this test is also useful.

The author waited for 4 years before he published his results correlating the operative and roentgenographic results with those found by this method. He controlled the method by proving that once the compression was removed, the area of hyperalgesia disappeared.

JOSEPH P. CASCINO, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Tonosclilography After Exercise. Боряк Ероу *Acta med. scand.*, 945, 30: Supp. 1.

Tonosclilography is the simultaneous automatic recording of the absolute blood pressure (ton) and the deflections showing the magnitude of the pulsatory pressure variations in the artery of the extremity (oscillography). These latter deflections as observed in the conventional Pachon type of oscillogram are widely used in the examination for peripheral vascular disease. The author's newly designed ink recording apparatus registers the systolic and diastolic blood pressures on a vertical curve between each tracing of the pulse variation in the vessel. At 30 second intervals the pressure curves fall to zero and follow each other on an endless paper band. A standard type of blood pressure cuff is used at different sites on the extremity. Other types of oscillograms and tonosclilometers are briefly described and discussed.

Oscillogram and oscillographic examinations of the resting extremity have been employed previously in studying peripheral vascular disorders but "this is the first time that the method has been used routinely on the exercised extremity." Various forms of graded exercises affected the oscillographic curves obtained from both normal individuals (77 cases) and patients with peripheral circulatory disease (660 cases). After exercise the pulsations and blood pressure were increased in the normal extremity and decreased in the extremity with organic occlusive disease.

The significant features of the tonosclilographs are (1) the change in blood pressure and the type and amplitude of the oscillations (2) the gradual subsidence of the reaction to exercise and (3) the length of time of the recovery phase. In all cases with peripheral organic vascular changes the recovery phase exceeded a minute, and in many cases it lasted as long as from 15 to 30 minutes. This recovery phase seemed to be directly proportional to the severity of the total mechanical vascular obstruction. Intermittent claudication is "always attended by vasoconstriction peripheral to the arterial obstruction and is probably passive or secondary to the fall in blood pressure and not due to a special tendency to spasm. This will affect directly the rapidity of the recovery phase. There was no difference in the curves obtained from patients with arteriosclerosis and those with thromboangiitis obliterans. Included in the pathologic material were 38 cases of coarctation of the aorta examined both before and after resection of the coarctation, 5 cases of pseudomalignant elastosis, and 9 cases of Raynaud's phenomenon.

The results of exercise oscillography agree with the arteriographically confirmed organic changes in

the artery. Other tests used for evaluation of the peripheral circulation were measurement of skin temperatures after heating of the body after reactive hyperemia following injections of tetra-ethylammonium bromide after local blocking of the lumbar sympathetic chain or spinal anesthesia, and the determination of circulation time with fluorescein. From this exhaustive study of 3,000 oscillographic examinations the author concludes that "tonosclilography after exercise" is a "new method for early diagnosis of organic disease leading to intermittent claudication and for differential diagnosis of organic and functional arterial disease."

This translated monograph of almost 300 pages is well written and the material is well organized and indexed. An extensive reference bibliography, many graphs, tables and case reports are used throughout the text. The report is exceptionally complete. For clinical application it is doubtful whether the results of tonosclilographic studies of peripheral vascular disease which require expensive special apparatus are of greater value than the results obtained by experienced examination with more simple conventional oscillogram and other tests which are used today.

FRANK V. TRER, M.D.

BLOOD; TRANSFUSION

Hemolytic Transfusion Reactions. MORRIS J. VANCE *Obstet. Anesthesiology* 945, 9: 345.

The development of blood banks has made the use of whole (citrate) blood transfusions a rather commonplace hospital procedure. And, as indicated by the author, although a compatible transfusion may often be lifesaving, an incompatible one may cause death. The purpose of this article is to review the etiology, signs, symptoms, prognosis, and treatment of hemolytic transfusion reactions, and present the experience of the Lahey Clinic with 3 such reactions. In Table I the author states the common indications for transfusion.

Although many errors related to grouping and cross-matching of the donor and recipient can be made, which result in the patient's receiving incompatible blood, in the author's experience clerical

TABLE I.—INDICATIONS FOR TRANSFUSIONS

1. Increase oxygen-carrying capacity hemorrhage, anemia, polycythemia
2. Restore blood volume in prevention or treatment of shock
3. Restore clotting mechanism to normal
 - A. Hypoprothrombinemia
 - B. Hymophilias
 - C. Platelets and other blood clotting elements
4. Correct hypoproteinemia, liver disease, nephritis, uric acidosis, carcinoma of stomach
5. Supply immune bodies in treatment of infectious diseases, septicemia, bacteremia, puerperal sepsis

TABLE II.—SOURCE OF ERROR IN BLOOD TRANSFUSIONS

- I Errors in grouping and cross matching
- A. False negative reactions—weak typing sera
 - 1 Low titer from outset
 - 2 Deterioration from improper storage
 - 3 Deterioration from bacterial contamination
 - B False positive reactions
 - 1 Pseudo-agglutination (rouleaux formation)
 - 2 Auto-agglutination
 - a. Cold agglutinins act on all bloods
 - b. Warm agglutinins
 - 3 Iso-agglutination—cold iso-agglutinins act only on certain blood
- II Clerical errors in handling of blood at bank
- A. Incorrect labelling of pilot tube
 - B Wrong blood released from bank
 - C. Mix-up in administering blood to patients

errors have caused the greatest number of hemolytic transfusion reactions. Table II lists the sources of error that one is apt to encounter in the administration of blood transfusions

A conscious patient who receives incompatible blood may show subjective signs and symptoms almost immediately or the reaction may be delayed and the initial manifestations develop several hours after completion of the transfusion. When incompatible blood is given to a patient under general anesthesia, however, there are no signs and symptoms to indicate what has happened unless by chance one should examine the urine and discover it to contain precipitated hemoglobin. In Table III the author classifies the various types of transfusion reactions

Once it is established that the reaction is caused by the recipient's having received incompatible blood vigorous treatment should be started at once. The author lays particular emphasis upon the fact that a preconceived plan of investigation should be immediately invoked to afford early diagnosis and prompt treatment.

Although urinary alkalization has not proved a panacea the author favors its immediate institution

TABLE III.—CLASSIFICATION OF TRANSFUSION REACTIONS

- I. Physical and chemical reactions
- A. Chemical
 - 1 Foreign material in apparatus
 - 2 Pyrogens
 - 3 Coagulative changes in transfused blood
 - B Physical
 - 1 Rapid administration of cold blood
 - 2 Air embolism
 - 3 Pulmonary edema from too rapid administration
- II. Allergic or urticarial reaction
- III. Hemolytic reactions (Intravascular agglutination and hemolysis)
- A. Intra-group type
 - 1 Rh factor
 - 2 "Cold hemagglutinins"

$\left\{ \begin{array}{l} \text{cirrhosis of liver} \\ \text{acute infectious} \\ \text{—virus pneumonia, paroxysmal cold hemoglobinuria} \end{array} \right.$
 - B Gross incompatibility
 - C. Dangerous "universal" group "O" donor
- IV. Transmission of disease—malaria, syphilis, infectious hepatitis

by the administration of sodium bicarbonate or potassium citrate orally or sodium bicarbonate sodium racemic lactate or sodium citrate intravenously. The fluid balance should be carefully watched and the retransfusion of compatible blood is important to counteract the severe hemolytic anemia associated with these reactions.

A new mode of treatment making use of A and B group specific substances to neutralize the alpha and beta agglutinins is discussed. If applied within the first few hours it may prove to be a most beneficial therapeutic endeavor.

Three cases of hemolytic transfusion reaction with anuria and hemoglobinuria are reported by the author. Two patients died and the third recovered. In the latter case 40 c.c. of Wittebsky's A and B specific substances were given intravenously in addition to the usual therapeutic measures.

EDWARD F. LEWISON, M.D.

SURGICAL TECHNIQUE

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Infections of the Hand J. B. LONDON, J. D. MONTGOMERY and J. C. SCOTT *J. Bone Surg.* 1948, 30-B, 409

The authors present a study of 793 patients with infections of the hand, who attended the Casualty Department of Radcliffe Infirmary Oxford England. Their cases have been classified in accordance with the anatomical structures and spaces of the hand, and attention is called to the economic importance of infections of the hand and the high loss of man-hours.

All infections of the fingers and hand have been classified according to the degree of infection. Infections of first degree presented throbbing and tenderness second degree infections presented more marked pain, redness swelling, heat, tenderness, and fluctuation third degree infections presented pain, redness, swelling fluctuation, heat, tenderness, and devitalized skin fourth degree infections presented the discharging hand pain was not so marked but sinus was present.

In 50 per cent of a series of 60 cases, no history of injury was given and it was deduced that the localized infection was blood borne. This conclusion seems most speculative since it is well known that small unnoticed abrasions of the hand are the most common progenitors of serious infections to follow.

The authors present a short description of the bacteriology and pathology of infections of the hand. They have also given an outline of the aims of treatment and the methods employed. Principles of treatment are based upon (1) the evacuation of pus, (2) excision of necrotic tissue, (3) primary suture of the wound whenever possible and in cases in which immediate skin coverage is not possible, early skin grafting. The operation is performed in a bloodless field. Dressings are changed infrequently and the involved part is immobilized in plaster. Two diagrams are presented—one showing incisions in relation to skin creases the other showing incisions in relation to the underlying structures. These incisions, with the exception of incisions for drainage of a thenar space abscess are essentially the same as those described by other authors. The preoperative operative and postoperative treatment are discussed as well as some of the individual cases, with photographs taken before and after surgery.

Emphasis is placed upon the well recognized benefit of rest of the involved parts by complete immobilization. In all instances, appropriate amounts of penicillin was given. The various stages of acute tenosynovitis are discussed, and methods of treatment are described. In Table 3 the authors show the average time of healing of pulp space infections distal palmar pulp infections, tendon sheath infections and paronychia.

The closure of infected wounds, after excision of necrotic and nonviable tissue is a radical departure from accepted surgical measures. This method of treatment of infections of the hand is believed to be radical and fraught with danger in the hands of the casual operator.

MORRIS J. DISTENFELD, M.D.

Streptomycin in Surgical Infections—Infections of Soft Tissues. EDWIN J. PULASKI, FRANK W. SPRICKER, JR., AND MELVIN J. JOHNSON *Ann. Surg.* 1948, 28, 46

This report, the fifth of a series dealing with the streptomycin therapy of surgical infections in United States Army hospitals is concerned with the results of this form of antibiotic therapy in infections of the soft tissues. Included in this report are 67 cases of cellulitis, 33 of which were associated with abscess formation, 30 cases of localized infection and 5 cases of specialized infection. Sixty-eight of the 103 patients were treated with streptomycin alone and 34 were treated with a combination of streptomycin and other bacteriostatic agents. Gram-positive cocci were the dominant organisms in 61 of the 103 cases. The *Staphylococcus aureus* and hemolytic streptococci were found in pure culture alone or in combination in 30 cases, and gram-negative bacilli were cultured alone in 16 cases. Mixed infections were present in 20 cases. Streptomycin was the only antibacterial agent employed in the treatment of 63 cases, the results being classified as good in 47, doubtful in 7, and poor in 14. The results in 34 cases treated with streptomycin in combination with penicillin or sulfadiazine, or both were good in 14 cases, doubtful in 4, and poor in 16. No reaction to streptomycin occurred in patients receiving less than 2 gm. of the drug daily, and only 8 of the 61 treated patients had minor undesirable effects of dizziness, nausea, or vertigo when this dose was exceeded.

The authors state that good results cannot be expected from streptomycin therapy unless certain conditions are met: the organism or organisms responsible for the infection must be streptomycin-sensitive; the drug must be given in adequate dosages; there must be little or no necrotic tissue present; and the blood supply to the affected site must be adequate. The cases in this series in which poor results followed streptomycin therapy were almost without exception cases in which these principles laid down by the authors were violated. Streptomycin apparently has its chief field of usefulness in acute infections complicated by cellulitis. It also has a field of usefulness in the therapy of acute gram-positive coccal cellulitides which are penicillin-resistant in which the patient has developed a penicillin-sensitivity reaction or in mixed infections in which the response to penicillin alone is not satisfactory because some organisms present are not penicillin-sensitive. Streptomycin applied topically gave indiffer

ent results and it is concluded that if local wound suppuration is not completely controlled within 72 hours after the topical application of streptomycin is begun the effect is probably not bacteriostatic. When streptomycin is used it must be given in adequate dosage. The optimal dose when it is used alone is from 2 to 3 gm daily the duration of treatment depending on the response. If treatment is discontinued too soon after a favorable response is apparent recurrence is likely. On the other hand if therapy must be continued longer than 14 days, the dosage should be reduced to avoid the risk of labyrinthine disturbances. The optimum dosage of streptomycin in combination with penicillin has not been worked out yet, but from present indications it will be considerably less than 2 to 3 gm daily now regarded as optimum when streptomycin is used alone.

EDMUND A. GORVETT, M.D.

ANESTHESIA

Sacrococcygeal Epidural Anesthesia in Obstetrical Practice (*L'anesthésie épidurale sacrococcygienne dans la pratique obstétricale*) HENRI DREUDONX, *Anesthésie Par* 1947 6 166

In succession, the author discusses the history of sacral anesthesia, its field of application, principle of action, technique, physiological action and the indications and contraindications to its use.

The principle of epidural anesthesia consists of a physiological interruption of nerve impulses conducted by the sacral nerves which innervate the soft tissues involved, i.e. the perineum, vulva, vagina, and the ischio-rectal fossae. By its application there is obtained an analgesia of the anus, rectum and urethra, as well as the parts above mentioned. The uterine body seems to escape anesthesia while anesthesia of the cervix is not constant.

The technique employed by the author is as follows: with the use of a blunt needle and with trocar in place, a puncture is made through the sacrococcygeal hiatus in the usual manner. The trocar is then withdrawn and a urethral catheter the same caliber as that of the trocar is introduced through the lumen of the needle and cautiously slipped into place. The distal end of the catheter is transfixed to the skin with adhesive tape. By means of a syringe led into the outer end of the catheter 25 c.c. of 1.5 per cent procaine is injected. The syringe is then replaced by a graduated container holding from 20 to 30 c.c. of the same anesthetic, which is allowed to flow into the catheter drop by drop as needed.

The physiological effect of the anesthetic occurs in from 20 to 30 minutes from the time of the injection and lasts from 1½ to 2 hours. Two actions are produced. The first of these is a constant action produced on the anus, vulva, perineum and vagina which is evidenced by a state of anesthesia, relaxation and decrease in tonicity of these parts. A less constant action produced is that of anesthesia of the vault of the vagina, the cervix and sometimes the body of the uterus.

The action on the uterine contractions in some cases is very marked, the amplitude is often greatly diminished, the rhythm less frequent and the contractions may sometimes entirely cease. In some cases the cessation of uterine contractions has been accompanied by varying degrees of uterine hemorrhage.

Action on the perineum is shown by an easy dilatation of the vulvovaginal canal which lessens the chance of perineal tears in cases in which the application of forceps is indicated.

With anesthesia of the perineum already obtained it is easy to suture perineal tears which may have occurred.

The author mentions several causes of failure to obtain epidural anesthesia. Failure to locate the sacrococcygeal hiatus may be due to the presence of an abnormal amount of subcutaneous fat in obese patients, to a deformity of the sacrum or the sacral canal as in spina bifida, to partial or total ossification of the membrane of Cathelin, or to a deformity of the upper end of the coccyx. Technical failure will result when the needle has not been introduced into the right place.

This type of anesthesia is indicated in cases of abnormal delivery, such as breech delivery in primiparas in whom versions or other operative maneuvers are indicated, proper relaxation of the soft tissues is afforded in such cases. It is indicated in cases in which spinal anesthesia is contraindicated as in cardiac and pulmonary complications or in long drawn out deliveries in which general anesthesia would prove fatal.

When epidural anesthesia retards labor by reducing uterine contractions, pituitary injections may be given to obviate the difficulty.

The length of time which elapses between the injection of the anesthetic and the attainment of satisfactory anesthesia contraindicates its use in those cases in which prompt anesthesia is demanded, as for example where danger to the life of the fetus exists.

BLACKWELL MARSHAM, M.D.

One Year's Experience with Intravenous Procaine
DAVID J. GRAUBARD, R. W. ROBERTAZZI and MILTON C. PETERSON, *Current Res. Anesth.*, 1945, 27 222

The authors report further on the clinical use of the intravenous administration of procaine for the relief of pain in 448 instances of traumatic, inflammatory and various other disease entities. The solution was prepared as a 0.1 per cent solution of procaine hydrochloride in isotonic saline solution to which has been added 1 gram of sodium ascorbate per 1,000 c.c. of solution. The average patient was observed to tolerate procaine better when given intravenously with vitamin C. A standard dosage of 4 mgm of procaine per kilogram of body weight in 20 minutes was used for each infusion.

The signs and symptoms observed during the intravenous administration of procaine were a sensation of warmth throughout the body sometimes ac-

accompanied by a flush over the head face and neck and followed by dryness of the mouth, a metallic taste, lacrimation, dilatation of the pupils, and light-headedness. Increasing the rate of flow or the concentration of procaine resulted in the manifestation of apprehension, dizziness, the sensation of trembling and sleepiness.

The types of cases in which this procedure was used as an adjunct to management are briefly summarized. Uniformly good results were obtained in relieving the pain of trauma except in cases of herniated intervertebral disc and in cases of myalgia of the upper extremities or of the shoulder girdle. In general the inflammatory conditions responded well except for lack of benefit in 7 cases of tic douloureux. Other conditions, including malignant disease and multiple sclerosis, varied considerably in response to the intravenous administration of procaine. However one case of established Parkinson's disease is reported with almost complete absence of tremors after 6 infusions over a 3 week period.

MARY KARP M.D.

d-Tubocurarine Chloride T. CYCIL GRAY *Proc. R. Soc. M. Lond.* 943, 4 559

The article is a critical appraisal of *d*-tubocurarine chloride in the light of 3 years' experience with its use in anesthesia. This is one of the least toxic drugs used in anesthesia as the heart, liver and the kidneys are unaffected by it. Nevertheless it is potentially one of the most dangerous. Any dose likely to be of service to the anesthetist will affect the respiratory muscles to some extent.

Certain points of technique are stressed. First and most important is the necessity to aid or assist respiration when *d*-tubocurarine has been given. A preliminary small dose as a test is strongly advocated. Intubation is carried out frequently to obviate the hazard of regurgitation of the stomach contents and to prevent inflation of the stomach.

It is the clinical impression that patients who have been anesthetized with the help of *d*-tubocurarine suffer less from shock than those who are subjected to deep or moderately deep anesthesia. The good

postoperative condition of the majority of these patients is accounted for by the fact that their vasomotor compensatory mechanisms are still active after a light anesthesia.

The author believes that *d*-tubocurarine is not the final answer but the absolute certainty of the results, its comparative nontoxicity and the ease of anesthesia in which it is used are factors which indicate a most significant step in management.

MARY FRANCES FOX, M.D.

The Vasodilating Action of Some Local Anesthetics.

R. BEVINGER. *Current Res. Anesth.*, 943, 37-197

The author discusses the fall of the blood pressure in spinal anesthesia. Fourteen dogs were studied, the blood pressure being registered in the usual way through a cannula inserted in the carotid and connected with a mercury manometer registered on a smoked drum. A dose of from 5 to 10 mgm. per kilogram of procaine was injected intravenously and the effects were noted.

The results demonstrated that the fall of the blood pressure is the result of vasodilatation which manifests itself in the free bleeding of the procaine injected areas following incisions or trauma. In an attempt to study the clinical structure with regard to this vasodilatation effect a number of other local anesthetics were studied and varying doses of these drugs were injected intravenously.

According to the observations made nearly all local anesthetics were found to lower the blood pressure by peripheral vasodilatation. The degree of this dilatation varied according to the chemical structure of these drugs without relation to their anesthetic potency. Intracaine was found to lower the blood pressure most, monocaine the least, and procaine and apothecaine lowered it to a middle position. Cocaine was found to be the only local anesthetic which in no case produced a fall in the blood pressure. In no instance was a material change in the rate or stroke volume of the heart observed, thus, the presence of cardiac depression was not considered the cause of a lower blood pressure.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

The General Theory of Stratigraphy (Teoria generale della stratigrafia) ALDO PERUSSIA AND CARLO BROCCI *Radiol. med.*, Milano 1948 34 449.

The characteristics of various modalities of stratigraphic examinations depend entirely on the theoretical study of the involved geometric problems.

The authors attempted to express in geometric terms the optimal relations between the focus, the object and the film. The various modalities of the stratigraphic method may be reduced to a single geometric formula which has been developed by the authors.

The stratigraphic method is especially adaptable to the study of the cranium, facial bones, the larynx and the chest.

The question arises: Is it possible by a proper selection of the position of the focus-object film to visualize a single layer of the object? In geometric terms the same question could be formulated as follows: What relations should there be between the focus and the film to retain the projection of the focus on the film during the movements of the system? It is this question that the authors attempted to answer by developing their geometric formula.

JOSEPH K. NARAT M.D.

Two Cases of Vertebra Eburnea of Apparently Primary Origin (Due casi di vertebra eburnea apparentemente primitiva) GIUSEPPE LACCHI *Radiol. med.*, Milano 1948 34 385.

The term vertebra eburnea is applied to a sclerotic process involving chiefly the body of the vertebrae and producing a variety of symptoms. Three groups of the lesion may be differentiated:

1. Opaque vertebrae of neoplastic origin. In descending order of frequency the following tumors may produce osteoplastic metastases: carcinoma of the prostatic gland, epithelioma of the breast, especially the scirrhous cancer of the stomach or the colon, hypernephroma and primary osteoblastic sarcoma of the spine. A contiguity of a neoplastic process may produce an opaque vertebra.

2. Opaque vertebrae caused by local or general pathologic conditions such as malignant lymphogranulomatosis, Paget's disease, blood diseases with osteosclerosis, syphilitic spondylitis, tuberculous spondylitis, streptococcal osteomyelitis, and Kummell's vertebral syndrome.

3. Opaque vertebrae which apparently have no relation to any other pathologic process.

Two cases belonging to the last group are reported by the author. The first patient, a woman 58 years of age, was afflicted with complaints of pains in the right upper quadrant of the abdomen. An eburnation of the first lumbar vertebra was found in addition to spondylarthrosis of the second and third

lumbar vertebrae. The rarity of opaque vertebrae on one hand, and the great frequency of arthritic conditions of the spine on the other, made relations between both conditions highly improbable.

Some nutritional disturbances affecting the calcium and phosphorus metabolism, avitaminosis or some toxic factors of exogenous or endogenous origin could have been responsible for the condition.

In the second patient, a woman aged 49, eburnation of the second lumbar vertebra was discovered in roentgenograms. The patient stated that she developed a sudden intensive pain in the lumbar region during parturition which took place 15 years prior to her admission to the hospital. Possibly the trauma caused a reflex in the sympathetic system with resulting vasodilatation and modifications of the local nutritional conditions.

JOSEPH K. NARAT M.D.

Some Considerations in the Treatment of Hemangioma in Infants and Young Children. EUGENE I. PENDERGRASS, JAMES C. KATTERJOHN AND JAMES B. BUTCHART *Am. J. Roentg.*, 1948 60 182.

The authors present their experience since 1938 in the treatment of 560 hemangiomas in 406 patients. The lesions had a wide distribution in location over the bodies of the patients.

Hemangioma of the skin or mucous membrane is a lesion familiar to every doctor. Whatever treatment is given should be early, that is, as soon after birth as possible or as soon as the blemish appears. A hemangioma is a localized hyperplasia of the cutaneous or subcutaneous vascular tissue. It varies in size and color. Vascular nevi may be separated on an anatomic basis into three groups: (1) flat or slightly elevated tumors composed of a superficial plexus of dilated capillaries, angioma simplex, nevus flammeus and port wine stain; (2) hypertrophic angiomas made up of an interlacing network of blood vessels of considerable size—angioma plexiforme and angioma simplex hyperplasticum and cavernous hemangiomas.

The technique employed may be divided into two parts: control of the superficial or dermal elements by roentgen therapy as the first part, and control of the deeper portions of the lesion by implantation of radon seeds or use of intermediate voltage therapy. The treatment is given over a period of months. When lesions occur on the scalp, around the eyes or in the region of the epiphyseal center of a bone, the family is advised about the possibility of damage to these structures. For small lesions located either around the eye, the lips, the nose or the labia, the authors prefer to use the Phillips unit using 44 kv. In every other situation the Chaoul apparatus using 45 kv. is preferred. The number of portals used depends on the size of the lesion and its shape. The skin target distance depends upon the depth of the

lesion. In port wine stains, the Phillips unit with 1.9 cm. distance is used. In the deeper or thicker lesions from 3 to 5 cm. skin target distance is used with the Chaoul unit.

Intermediate voltage from 75 to 155 kv. is used in the instances in which the lesion is large and bulky. Most of the small and deep-seated hemangiomas are treated with radon after skin discoloration has been removed by roentgen therapy. With intermediate voltage from 1 to 3 mm. of aluminum filtration with a half value layer of from 2.4 to 4.6 mm. of aluminum is used the filtration of the radiation with the Phillips and Chaoul units ranges from unfiltered to 0.2 mm. of nickel. The half value layer of the radiation is 2.4 mm. of aluminum with the Chaoul apparatus, and 0.3 mm. of aluminum with the Phillips unit at contact. The lesion is given from 300 to 400 roentgens (as measured in air) through as many portals as are required to cover it. The portals do not overlap. The patients are seen at intervals of 4 to 6 weeks. Usually from 3 to 7 treatments are required and usually less than 1,500 roentgens are given. Seventy five per cent of the patients treated with the Chaoul apparatus receive less than 1,350 roentgens and 95 per cent receive less than 1,750 roentgens the treatment time extending over a period of 18 months. The most deeply situated portions of the lesions are treated with implantation of radon seeds of from 0.1 to 0.5 mc. of strength through multiple portals. In general all lesions respond well if treated early.

FRANK L. HUMBY, M.D.

Statistical, Pathogenetic, and Clinical Considerations on Radionecrosis of the Mandibular Bone (Considerazioni statistiche, patogenetiche e cliniche sulla osteoradionecrosi mandibolare) FRANCO PIZZORRI. *Radiol. med. Milano*, 94:5, 341-351.

This study is based on 48 cases of bone necrosis observed among 153 oral carcinomas which were more or less connected with the mandibular gum were treated at the Institute of Radiology of the University of Milan, and had been followed up for a considerable period. The bone necrosis usually sets in suddenly months or years after radiotherapy is manifested clinically by severe pains, and is often preceded, sometimes accompanied or followed, by necrosis of the overlying soft tissues. It results in the formation of sequestra which are eliminated spontaneously or removed surgically. The course is prolonged for months and healing begins only after elimination of the sequestra. Some authors attribute the bone necrosis to the direct action of the rays on the living cells of the bone but most authors believe in a vascular pathogenesis in which the rays produce changes in the vessels of the bone or in those of the overlying periosteum and mucosa. Of the 48 cases, 38.5 per cent occurred between the ages of 40 and 70, and 65 per cent after the age of 70.

Two treatment methods were used the first consisted of intraoral radium therapy followed by the removal of involved lymph nodes and the application of an external radium apparatus providing from 30 to

40 U D the second consisted of intraoral radium therapy only.

Bone necrosis occurs rarely when the calculated dose remains below 1.4 destroyed millicuries per square centimeter (with or without external apparatus) but appears suddenly and frequently when this dose is exceeded. It occurs with about equal frequency with or without an external apparatus when the dose is between 1.4 and 2 mc. per square centimeter and it occurs constantly when the dose approaches 3 mc.

Eight cases were preceded by tooth extraction in the involved zone from 25 days to 12 months previously. In 2 of these cases the extraction was done for extraneous reasons and was soon followed by bone necrosis. In the other cases the chronologic relationship was rather close and the interval was marked by local dystrophic or inflammatory phenomena which gave the impression of a cause and effect connection. These patients had been given medium doses and one had received a particularly low dose. Twenty-seven cases were preceded by necrosis of the overlying gum often denuding the bone the patients had received an average dose of 1.7 mc. Of the remaining 21 cases, 5 were preceded by dental extraction and 4 by inflammatory phenomena with fistula formation. In 12 the necrosis of the mucosa was present at the time of elimination or removal of the sequestrum the patients had received an average dose of 1.5 mc.

It is to be noted that bone necrosis has occurred 5 or 6 times less frequently when treatment consisted only of the application of an intraoral apparatus instead of the introduction of radium needles. This may be due to the fact that the needles are closer to the periosteum or produce more mechanical damage to the gingioperiosteal vessels.

The following conclusions appear to be justified. The medium global dose of radium exerts a marked influence on the incidence of bone necrosis which is rare when the dose is below 1.4 mc., more frequent when the dose exceeds 1.4 mc., and exceedingly frequent when the dose approaches 3 mc. Needles inserted close to the surface of the bone especially those of high potency seem to exert a marked damaging effect on the vital ty of the bone. The adjunction of an external radium carrying apparatus, usually sub-mandibular does not seem to influence the incidence of bone necrosis.

RICHARD KENEL, M.D.

Laryngeal Chondronecrosis Following Roentgen Therapy WILLIAM A. GOODRICH and MARGARET LEE. *Am. J. Roent.* 94:5, 60-62.

Healthy laryngeal cartilage is protected by a normal mucosa and the perichondrium will withstand infection with moderate fractionated x-ray dosage. However when adult cartilage is infected or traumatized extensive necrosis and sequestration may occur. Chondronecrosis is rather rare in small or early carcinoma. It is more common in advanced or extensive growths for the tumor invades the adjacent tissue and obstructs the venous and lymphatic capillary flow thereby causing mucosal edema. The edematous mucosa tends to ulcerate and affords

access of bacteria into deeper tissues. As a result of this spreading infection the perichondrium becomes involved with involvement of the cartilage. Such a process may occur with or without x ray therapy according to the extent of the lesion.

From 1932 to 1946 205 cases of laryngeal tumors were studied. There were 28 cases of laryngeal necrosis. The chondronecrosis was dependent upon the following factors: (1) the time interval between the last x ray treatment and the recurrence of the necrosis; (2) the site and extent of the involvement of the tumor; and (3) any previous surgery such as laryngectomy that has been done prior to the x ray therapy.

Chondronecrosis in the majority of cases (23) was observed within 6 months from the time of treatment if finished. Seventeen patients showed a fixation of the arytenoids which suggested that these may have been the initial site of the chondronecrosis. Thyroid cartilage necrosis did not appear to be the initial site in the present series of cases. Chondronecrosis was slightly more severe in the cases in which the epiglottis was involved. Most cases of cured cancer of the epiglottis showed a definite deformity of the cartilage which indicated a healed area of chondronecrosis. In the series of 25 patients with carcinoma of the epiglottis which had been treated 6 developed a marked necrosis of the cartilage.

The extensiveness of the lesion has a definite influence on the tumor. Chondronecrosis was observed in 16 cases in which the arytenoids were fixed. In 2 of 7 cases with laryngeal fissure chondronecrosis developed. There was 1 case in which hemilaryngectomy was done 2 weeks after a tumor dose of 7,800 roentgens was given. The removed portion of the larynx showed only radiation reaction without evidence of necrosis or persistent carcinoma. However after the operation chondronecrosis developed promptly in the remaining portion of the larynx. The second patient was subjected to partial bilateral removal of the thyroid cartilage before x ray therapy and developed a chondronecrosis of the remainder of the cartilage.

Laryngeal edema was apt to occur when larger fields a daily dose and a shorter period of treatment were used. The dosage given to the 28 patients who developed chondronecrosis was as follows: 14 received a tumor dose of from 5,500 to 6,000 roentgens and 10 were given a tumor dose of from 6,000 to 7,000 roentgens. The average effective tumor dose was between 5,500 and 8,000 roentgens. The treatment time in the majority of cases ranged from 35 to 45 days and the daily dose from 100 to 150 roentgens, which was given to two opposing laryngeal fields. In several cases in which there was marked edema prior to therapy the dosage was lowered to 50 roentgens and the size of the field was cut to about 6 by 8 cm. Patients with laryngeal carcinoma were generally given from 6,000 to 7,000 roentgens in air in a 6 week period to two lateral fields directed somewhat obliquely toward the larynx. Central

overlapping of radiation was avoided with a 1 cm lead strip a 200 kv unit was used 100 roentgens were given to each side the fields being 5 by 8 cm. each. If cervical nodes were present they were treated separately.

Reactions during the course of treatment varied. Treatment was usually interrupted between 1,400 and 1,800 roentgens to each of 2 fields if a pseudodiphtheric membrane developed and was resumed after several days when the inflammation began to subside. The treatment was carried to completion if the initial membrane did not develop until 2,500 roentgens had been given to each field, i.e., approximately 3,000 roentgens to each field. Sometimes treatment had to be interrupted to allow the edema to subside and in some cases tracheotomy was done before treatment. In such instances the daily dose was much smaller generally between 50 and 75 roentgens.

The prognosis of chondronecrosis of the free portion of the epiglottis is much more favorable than that of the rest of the laryngeal cartilages, for any necrosis of the former portion can readily be expectorated. Arytenoid chondronecrosis has a bad prognosis with an upward drainage of infection and necrosis.

Chondronecrosis can be prevented to some extent by the extensive use of chemotherapy. In several instances of extensive carcinoma with marked infection chondronecrosis was prevented by the oral use of penicillin for several weeks prior to the treatment. It is quite possible that the Arbuckle procedure (total removal of the cartilage by laryngectomy) would be helpful. MAURICE D. SACIN, M.D.

Radiology of the Persistent Thyroglossal Duct (Zur Roentgenologie des Ductus thyroglossus persistens)
W. GUNZERT *Acta radiol.*, Stockholm, 1948, 29, 343.

The author reviews the embryology and anatomy of the thyroglossal duct, discussing at length the development of the four main types: (1) incomplete duct with fistula communicating with the foramen cecum; (2) incomplete duct with exterior fistulous communication; (3) a complete median tract, with or without cystic formation; and (4) a cyst in a blind remnant of duct with neither exterior nor interior communication.

The roentgenologic diagnosis of these conditions is discussed. A differential diagnostic list is included and throughout the entire discussion an excellent list of references is given. Four case histories are given as diagnostic problems for roentgen study. The following suggestions are made regarding the diagnostic technique:

There are a large number of radiopaque media which can be used for injection into the tract usually by means of a cannula among which are barium bismuth sodium iodide sodium bromide and the newer substances thorotrast and iodized oil. None of these contrast media are completely satisfactory at all times. When there is a complete median tract a more viscous medium must be used to prevent spilling out as quickly as it is injected. The site of injection

varies with the type of the persistent structure. In an incomplete inner fistula an injection of medium can be done through the foramen cecum. This is best done under pressure with a cannula because sometimes the fistula ends in a blind cyst filled with cholesterol crystals. Injection into an incomplete outer fistula is more simple and is done under some pressure to outline a terminal cyst. It is difficult to outline the complete median tract which is patent at both ends. One way of doing this is to inject from the exterior aspect sufficient medium to fill the tract and cyst, if present, so that the medium escapes through the foramen cecum. The patient will state that there is something in his throat at this point and a roentgenogram taken at the same time should show a completely filled tract. In the cases of cysts with neither outer nor inner fistulous opening a puncture is made in the midline with a sharp needle which is left in place after the injection and a roentgenogram is taken to check the actual filling of the cyst. One reference is given to x-ray and radium treatment of the thyroglossal duct.

JACK C. MACMILLAN M.D.

Angiocardiography in the Diagnosis of Congenital Heart Disease. K. D. KRELL. *Bull. J. Radiol.* 945, 21, 350.

The importance of accurate diagnosis in congenital heart disease has of recent years increased with the advent of surgical methods of treatment. Angiocardiography provides a method whereby this necessary accuracy may be obtained. In the present article acyanotic congenital heart disease only is discussed since it is considered that this group of cases presents most commonly the diagnostic difficulty in relation to surgical treatment.

The technique is outlined briefly. After preliminary sensitization tests the child is anesthetized with cyclopropane and oxygen by means of an intra-tracheal tube.

The patient is placed on a cassette tunnel in the anterior oblique position. A vein in the left ante-cubital fossa is dissected out and a large cannula is inserted. After a preliminary film from 15 to 20 c.c. of 70 per cent pyrolosil is introduced within 2 seconds into the vein. Eight films are exposed in rapid succession in the next 12 seconds. Normal saline is infused through the cannula for the 15 to 20 minute period to aid in excreting the contrast agent. The procedure is repeated with the patient in the antero-posterior position. Films are taken at 65 kilovolts, 200 milliamperes and 1/20th second exposure.

The author presents the findings in a normal angiocardiogram. He also reports 5 cases of children presenting abnormal angiocardiograms, coarctation of the aorta, patent ductus arteriosus with complete heart block, patent ductus arteriosus with pulmonary stenosis, patent ductus arteriosus with patent inter-auricular septum and patent interventricular septum.

It is believed that angiocardiography should be used in any case of congenital heart disease in which operation is being considered since it may provide

proof of the suspected lesion and also reveal other lesions.

FRANK L. HUMBERT M.D.

Radiation Therapy of Malignant Tumors of the Testis. T. LYCUTTA, WILLIAM A. EVANS, JR., and JAMES C. COOK. *Radiology* 1945 51: 177.

Review of the literature indicates the incidence of neoplasms of the testis to be between 0.5 and 1.5 per cent of all malignant neoplasms. The authors present a statistical analysis of the factors influencing the survival rate in 110 cases of malignant tumors of the testis observed at Harper Hospital, Detroit from 1923 to 1947. The patients were in most instances treated by simple orchiectomy followed by extensive irradiation operation having been omitted only in extensive metastases were present.

Irradiation was started within a few days after the operation and applied not only to areas of regional invasion but also to areas of probable distant extension regardless of whether or not there was obvious evidence that metastasis had already occurred. The treatments were grouped at from 8 to 10 week intervals. The first series included four or five portals for the pelvis and groin, three or four portals over the para-aortic lymph nodes, 2 for the supraclavicular and cervical nodes, and 2 portals for chorioepithelioma of the kull. In the second and third series of treatments only the pelvis and abdomen were irradiated. The portals were large and full doses were delivered in a single session per portal, at the rate of 500 rads per day. The factors used were usually 200 k. half-silver layer 1.0 mm. of copper 50 cm. skin target distance intensity 15-20 roentgens/min. The full dose amounted to 100 per cent SUD for the first series, 90 per cent for the second, and 80 per cent for the third with 100 per cent SUD set at 525 roentgens in air (785 roentgens with backscatter). In some heavy patients the factors chosen were 500 kv. 7 mm. of copper 60 cm. skin-target distance at 20 roentgens/min. In these cases the dose was 675 roentgens/air (925 roentgens with backscatter). This gave a tumor dose of 110 per cent SUD for the first series and 70 per cent SUD for the third.

The age of the patients treated ranged from 17 months to 72 years with the peak incidence of the tumors (71%) being between 25 and 45 years. The authors do not present the histological classification of their cases but refer to the general agreement in the literature that malignant teratoma tends to occur in younger people reaching a peak incidence at the age of 23 in the series of Friedman and Moore and carrying a poor prognosis whereas seminoma had a peak incidence at the age of 30 in the same series and a better prognosis.

The authors studied the 2, 5, 10, and 15 year survival rates in their series from a number of clinical aspects. They found that the patients presenting themselves for treatment in the fourth decade had the highest survival rate for all periods, although the frequency of metastases at the time treatment was initiated was as great as in some other age groups. The results were poorest in the very young.

Cryptorchidism (8%) other scrotal abnormalities (14%) such as hydrocele varicocele or epididymitis and gynecomastia (7 cases) did not appear to influence the prognosis unfavorably. Instead patients with these complications were apt to have their attention called to the tumor at an earlier stage and hence to receive more prompt treatment. About 70 per cent of this group of patients attained 5 year survival. In the same way a history of recent trauma (30%) was not unfavorable for it too tended to bring the patients for examination more promptly at a time when fewer of them showed obvious metastases. Sixty-one per cent of these survived 5 years.

On the other hand pain was an unfavorable symptom for those patients complaining of it showed a slightly higher incidence of metastases at the start of treatment and a much poorer survival rate (48% at 5 years and 28% at 10 years) than those with a painless swelling of the testis (62% survival at 5 years and 51% at 10 years).

As the duration of the acute progressive symptoms lengthened before treatment was sought, there was a steady increase in the per cent of metastases found at the time of first examination and decrease in the ultimate survival rate. Patients who received treatment within 3 months of the onset of symptoms had a 5 year survival rate of 71 per cent, compared to 42 per cent for those who had waited a year.

Forty three per cent of the patients had clinically evident metastases—para-aortic, supradiaphragmatic inguinal pulmonary or generalized—when they first reported for treatment. Yet the statistical analysis showed that even these patients had some chance for long time survival for 31 per cent were living 2 years later, 29 per cent at the 5 year period, 19 per cent at 10 years and 7 per cent at 15 years. The survival figures for the group without obvious initial metastases were of course much better, 91 per cent at 5 years, 78 per cent at 5 years, 66 per cent at 10 years and 50 per cent at 15 years. If all the patients are taken together, 55 per cent lived 5 years, 43 per cent 10 years and 33 per cent 15 years. The 2 year survival rate was found to be a good prognostic index for 5 year survival.

These figures agree well with those reported in the literature for patients with a malignant testicular neoplasm treated by combined orchectomy and extensive irradiation. The 5 year survival rate from various sources averaging about 50 per cent, with a low of 25 per cent for malignant teratomas (Schuts and Leddy, 1946) and a high of 67 per cent for seminoma (Nash and Leddy, 1943). They are in sharp contrast to the over-all survival rates recorded following orchectomy only. The highest 5 year rate being the 34 per cent reported by Higgins and Blichert in 1939.

LILLIAN DONALDSON M.D.

Röntgen Therapy of Carcinoma of the Female Urethra and Vulva. FRANK BUSCHKE and SIMON T. CANTRELL. *Radiology* 1948, 51: 155

On reviewing the literature the authors found that external roentgen therapy was not used in a sys-

tematic way for the treatment of the primary lesion of either carcinoma of the vulva or urethra. Indeed by some it was branded as an inadequate weapon in these neoplasms if used within limits that avoided deleterious by-effects. The authors believe this to be a misconception based on an insufficient appreciation of the importance of the quality of the radiations used. They agree that low voltage irradiation will not be tolerated by the vulvar mucosa in doses necessary for sterilization even if the entire tumor can be irradiated homogeneously at such voltage, but their own experience with a small group of cases followed up over a period of years indicates that with radiation in the 200 kv. range a tumor-sterilizing dose can be delivered which is still tolerated by the sensitive vulvar mucosa.

The authors are of the opinion that comparatively small carcinomas originating in the labia, clitoris, or posterior commissure are better treated by radical excision, radiation therapy being reserved for the more advanced stages of these lesions in which surgery cannot be expected to remove the entire lesion because of diffuse extension into the neighboring subcutaneous structures. They find the curability by radiation therapy even of advanced lesions in these locations reasonably good because of the comparatively low degree of differentiation of the epidermoid carcinomas usually encountered there. They also consider radiation therapy as the procedure of choice in the treatment of even small lesions in the penurethral portion of the vulva, the surgical removal of which would necessitate the destruction of the urethra, often with poor functional results.

Carcinomas originating in the urethra itself present a different histologic picture since they frequently originate from glandular structures and undergo metaplasia into adenocarcinoma, often exhibiting less radiosensitivity than vulvar carcinomas. However, neoplasms in this region give symptoms at an early stage when tumor volume is still small and can therefore be included in a small field of irradiation. Hence the reaction can be kept within reasonable limits of intensity and late tissue changes are minimized while satisfactory function is maintained.

Therefore the authors selected early carcinomas of the urethra and advanced carcinomas of the vulva for radiation therapy. The vulvar group was comprised of 8 cases too advanced for radical surgery. The patients ranged in age at the time of treatment from 39 to 82 years. Of them 5 are well, 5 are 2, 5, and 15 years respectively. Three who already had obvious regional metastases at the time treatment was undertaken, were dead in a little over a year. The doses in the controlled cases varied between 4,000 and 4,500 roentgens/skin given in from 20 to 26 days through fields measuring from 20 to 35 sq. cm. Mucosal reaction developed between the sixteenth and twenty-fifth days following the beginning of treatment, and was not completely healed until the forty-second to forty-fifth day. Permanent mucosal changes were minimal.

Four cases of true carcinoma of the female urethra including 1 undifferentiated epidermoid carcinoma and 3 adenocarcinomas, are presented. Two other cases with treatment for carcinoma but on later histologic review classified as urethral caruncles are also recorded for the late condition of the mucous membrane after heavy irradiation. These carcinomas received at least roentgen therapy directed against the urethral opening through one field 3.5 cm. in diameter with the beam coinciding with the axis of the urethra.

All of the patients in this series were treated with 200 kv. radiation with from 1 to 2 mm. of copper filtration. The first patient aged 61 received skin dose of 565 roentgens in 2 days and developed a massive primary reaction lasting from the twentieth to the sixty-fourth day which at times necessitated the use of an indwelling catheter and was productive of a small area of late necrosis 1 year after treatment. However the patient is well with good function 5 years after irradiation but with a mild grade of urethral stricture and moderate mucosal atrophy and telangiectasis. The changes are sufficient to necessitate constant lubrication and scrupulous cleanliness of the parts to avoid intercurrent infection and the author considers the case to have been overtreated. The 3 patients with urethral adenocarcinoma aged from 57 to 65 re-

ceived only 5,200, 4,600 and 5,000 roentgens/skin in 22, 32 and 29 days respectively. The first of these developed a mild mucosal reaction between the twenty-eighth and fifty-first days with a small area of late necrosis at 6 months, and has been well now for 4 years with good function and very slight mucosal atrophy. The 2 other patients received, respectively 4,600 roentgens in 32 days and 5,000 roentgens in 29 days and developed mild mucosal reactions from about the thirty-sixth to forty-sixth days followed by excellent healing. One has been well for 2 years the other is yet followed up for only 1 year shows the primary site to be healed but has required excision of 2 metastatic nodules in the adjacent labium and skin.

In reviewing the immediate and late results in this small series of cases of urethral carcinoma the authors believe that a total dose of around 5,000 roentgens/skin in about 25 days is tolerated by the mucous membrane for the small fields necessary in this type of lesion and is apparently sufficient for treatment. They regard the limit of tolerance as not over 5,200 roentgens/skin and warn that the reaction of the tumor and surrounding mucosa in this location appears late after the end of adequate treatment and cannot therefore be used as a guide in the conduct of therapy for these rare lesions.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Trophic Nerves and Dupuytren's Contracture (Trophische Nerven und Dupuytren'sche Fingerkontraktur) PAUL REICHEL. *Chirurg* 1946 17-18 97

The author presents the question as to whether or not there are truly trophic nerves.

Three possibilities might explain the trophic changes which occur following the interruption of a nerve. The changes may be produced by a vasomotor effect, by traumas to which the denervated part cannot react normally because of the anesthesia or absence of normally protective reflexes, or by the lack of certain, at present unknown influences exerted by special trophic nerve fibers.

The author is an adherent of the third theory and justifies his opinion by pointing out the appearance of corneal ulcers following gasserian ganglion resection which he does not believe can be caused simply by trauma or a vasomotor effect.

Reichel has observed 5 cases of Dupuytren's contracture following injuries to the ulnar nerve. In all of these the nerve injury was unilateral, but the connective tissue changes were bilateral. This he feels is easily explained on a nervous basis. Furthermore, he suggests that an accurate anamnesis in cases of Dupuytren's contracture will often reveal a history of trauma, sometimes remote in time and location to the ulnar nerve. He concludes that this entity is a trophoneurosis. WILLIAM C. BECK, M.D.

A Case of Juvenile Dupuytren's Disease (Su un caso di morbo di Dupuytren giovanile) VITTORIO FINA. *MON. Ann. med. nov. Roma*, 1947 52 97

The author describes a case of Dupuytren's disease in an 18 year old boy in whom this condition had been present for some years. He first noted difficulty with the small finger of his right hand and this gradually increased. The next three fingers were then also gradually affected in a similar manner. When examined he showed marked flexion of all four fingers and only the index finger could be extended to any degree. The usual cordlike structures were palpable in the palm.

Under local anesthesia an excision of the palmar aponeurosis was performed with good results. The author cautions against the addition of adrenalin because of the reported cases of gangrene following its use in association with local anesthesia of the extremities. Early diagnosis is stressed as well as the necessity of resorting to surgery before ankylosis of the phalangeal joints occurs.

The literature on the subject is reviewed. Felix Plater first mentioned this condition in 1821 and Cooper recognized it in 1831 but it was first accurately described by Dupuytren in 1832.

LEONARD J. FROEDT, M.D.

Surgical Repair of the Hand. New Material for Plastics of the Hand. Preliminary Communication (Cirugía reparadora de la mano. Nuevo material para plásticos de la mano) CARLOS A. DERRIEN. *Dis. med. B. Air* 1948 20 927

The material used by the author in 2 cases consisted of strips of bovine fascia which are very pliable and extremely well tolerated by the organism. In fact, the favorable results obtained with this material tend to make him prefer it to autografts and to base great hopes on its possibilities. The advantage of obtaining a graft without having to increase the risks and the stages of the operation and the ease with which large amounts of this fascia can be obtained have led to the creation of a simpler technique for extensive tendinous plastic operations.

Four years before admission a woman of 40 suffered a wound of the digitopalmar fold of the annular and index fingers of the left hand which left these fingers stiff and without flexion because the corresponding tendons were severed. Under local anesthesia in the middle third of the forearm and block of the nerves at the wrist an incision in the form of an S was made and it was found possible to reunite the two ends of the tendon of the index finger according to Bunnell's technique. The suture site was enveloped in a sheath of bovine fascia to avoid adhesions. The distal tendon of the ring finger had disappeared therefore an external and lateral incision was made and a strip of fascia was sutured to the third phalanx. Two strips of the same material were placed around the other two phalanges to serve as pulleys and the proximal end of the first strip was then sutured to the remaining tendon. The skin was closed with linen sutures and a dorsal plaster of Paris gutter was used for immobilization with the fingers in semiflexion. Unfortunately the patient developed ischemia of the third phalanx and later its distal portion was eliminated but a good stump was left. Recuperation was estimated at 60 per cent of normal.

A man of 27 suffered a wound of the lower third of the back of the right forearm which resulted in the loss of extension of the three last fingers. Under local anesthesia at the middle third of the arm an arclike incision was made 20 cm in length and scar tissue was found to envelop the severed ends of the tendons for about 8 cm. The scar tissue was resected and the tendon stumps were freed until healthy tissue was reached. Two parallel strips of bovine fascia 8 cm long were used one for the tendons of the middle and ring fingers and the other for the little finger. To avoid adhesions with the superficial tissues, the strips were enveloped in a vein taken from the cutaneous flap. The extremity was kept at rest in a plaster of Paris gutter which was removed after 15 days. Recuperation of function was 100 per cent. RICHARD KEMEL, M.D.

Repair of Cicatricial and Dupuytren's Contractures of the Hand. HART MAY *Plast. Reconstr. Surg.* 948, 3: 459.

The common causes of cicatricial contractures of the hand are shrinkage of the skin and fascial structures from prolonged and rigid immobilization of the hand in faulty position after injuries, infections, and burns. The vast majority of these contractures could be avoided if the hand were immobilized in a position of function. When the wrist is held in flexion, that is, in wrist drop and allowed to remain in this position, the extensor tendons are maximally stretched; hence, they cannot be relaxed further if an attempt is made to close the hand to make fist. This prevents full function of the flexor tendons. The fingers are drawn in hyperextension in the metacarpophalangeal joints, the thumb is drawn back to the side of the hand and the collateral ligaments of the metacarpophalangeal joints are relaxed and shortened. There is a rapid shrinkage of the collateral ligaments, which prevents normal gliding of the phalangeal joint surface over the head of the metacarpal bone. The posterior part of the joint capsule is contracted. The entire lumbrikal system is upset. This is the well known picture of the claw hand.

This contracture can be prevented by immobilizing the hand in the position of function, namely extension or cocked up position of the wrist, midflexion of the metacarpophalangeal and interphalangeal joints, and abduction and opposition of the thumb. If contractures have developed, those of the thumb should be overcome first by conservative methods in the form of elastic splinting with the incorporation of elastic traction, in association with occupational and physical therapy, or by operative reconstruction. Burn contractures present some of the most difficult problems of reconstructive surgery. The difficulty is primarily because of the depth of the scar, while in other parts of the body, severe burn does not cause any functional damage since the epithelium regenerates from the remaining layer of the cutis, on the hand particularly at the dorsum, second degree burns quite frequently are followed by severe contractures from keloidlike scars. The contractures of the deeper structures, namely the fascia, ligaments and tendons are most disastrous. Most of these can be avoided if the hand is properly immobilized during the healing stage and skin grafting is employed early. This is true especially in third degree burns.

The principle in correcting these contractures consists of excision of the entire cicatricial surface tissue followed by repair of the contracted fascial structures, and closure of the defect with a graft or flap. A free graft, however, will not take on naked tendons, bones or joints, therefore every effort should be made not to expose these structures during the excision of the cicatrix.

The operation is carried out in a bloodless field, the use of a pneumatic tourniquet. The entire incision is outlined with an incision and the depth of the incision depends upon the depth of the scar tissue. In a second degree burn the excision of the cicatricial

skin is carried at the level of the subcutaneous veins. Care should be taken not to injure them. In third degree burns excision of the scar tissue is done at the level of the deep structures. However, care should be taken not to expose the tendons if the use of a free skin graft is considered. In the majority of cases, exposure of the tendons can be avoided by removing the scar tissue over the tendons in layers and stretching of the tendon is gradually done by cross-cutting the covering tissue in numerous places until full or almost full relaxation of the tendons can be reached. The forearm and hand is then immobilized in the position of function. Oftentimes, a wire is passed through the terminal phalanx and fastened to the end of the splint. The splint is bent until the fingers are in 45 degree flexion in all the joints. The defect is then covered with a full thickness graft or with a thick split graft. If the tendons are exposed, the use of a pedicled flap is the only choice. Sutures are removed after 8 days and the splint remains in place for another 6 days. Warm saline hand baths are administered daily with active and passive motion exercises while the hand is in the water. The splint is discarded entirely 3 weeks after the operation.

Dupuytren's contracture of the palmar aponeurosis must be classed among diseases of unknown origin. The disease progresses gradually to involve not only the palmar part of the aponeurosis but the fourth and fifth fingers, less often the other fingers, but very rarely the thumb. It is impossible to restore mobility of the fingers if the latter are arthritic and ankylosed. Insufficient removal of the diseased structures invites recurrence. The peculiar process is not confined to the palmar fascia alone but often the skin over the diseased fascia is involved so that recurrence of the contracture in the skin occurs, even after removal of the underlying fascia. Because of the involvement of the skin and the fascia both should be removed when involved, and only after complete removal of the fascia and fascial extensions can recovery be expected with return of good function.

The excision of the involved fascia and the involved skin must be radical. For example, it must include the fascial extension over the thenar region, the extension to the second, third, fourth, and fifth fingers. It must include the fascial extension, which connects the fascia with the underlying tendons and tendon sheaths and also the diseased skin island. Great care should be carried out in the dissection to avoid injury to the digital nerves and vessels. The tendon sheaths should not be opened.

The forearm, hand and fingers are immobilized in the position of function and a pressure dressing is applied. If the excision results in the exposure of the tendons, closure of the defect with an abdominal flap is advisable.

JAMES E. KARRAS, M.D.

Hodgkin Disease 1832-1947. HERMAN A. HUNTER and MARTIN B. DRYAN *Cancer Res.* 1948, 8: 49

Malpighi first described this disease in 1661. Hodgkin evaluated this disease as a clinical entity in

1832 in 1872 Langhans noted the presence of giant cells in lesions from this disease in 1902 Dorothy Reed made her classic contribution to the histopathology of the disease. Scores of names have been applied in the past but the official name now is simply Hodgkin's disease. The recorded incidence in the United States varies from 0.5 to 2.5 per 100,000 living population. Increased incidence has been reported in the last two decades possibly because of the increased use of biopsy as a diagnostic procedure. The disease has a world wide incidence. It can occur at any age but is most frequent in young adults. Males are affected twice as often as females and in childhood the ratio increases to more than 4 to 1. It has been said that the disease occurs more often in more than one member of a family than can be accounted for by chance alone.

Hodgkin's disease is considered to be a disorder of the entire reticuloendothelial system but it affects the lymphatic system primarily. The rate of spread from node to node is variable and progressive with exacerbations and remissions. Some say the deeper nodes are really the first to be involved. The nodes are involved in chains and may be discrete or matted. The younger growths show a uniform gray bulging surface on section. The older ones are harder and show opaque intersecting yellow lines of fibrous tissue. There is little necrosis or suppuration. Splenomegaly is frequent and hepatomegaly less so. Gastrointestinal lesions are rare. Other abdominal organs are occasionally affected but it is chiefly the abdominal nodes which are diseased. The mediastinal nodes are often involved and there may be spread to the heart and lungs. Pleural effusions are frequent. Bone lesions are a very frequent late manifestation. Direct invasion of the nervous system is rare but neurological symptoms are fairly common as the result of lesions of the meninges and surrounding bone. Varied and perplexing skin lesions often occur. The primary site is very difficult to evaluate because the disease is seldom diagnosed until it is moderately far advanced. The earliest microscopic change is said to be a proliferation of reticulum cells in lymph nodes. The spaces in the nodes are filled with these cells and with lymphocytes. Then there is a development of many eosinophiles multinucleated cells and large mononuclear cells followed by a conversion or degeneration of these cells into fibrous tissue. There is a reduction of lymphoid tissue of the normal type in involved organs and in uninvolved organs. There are various classifications of different phases of the disease such as paraganuloma granuloma and Hodgkin's sarcoma. Some believe the first two are chiefly inflammatory in nature while the latter is frankly malignant but different nodes in the same patient at one time may show each of the above "stages."

Many authors relate the origin of Hodgkin's disease to recent infections about the head or respiratory tract but this may be an effect and not a cause. Tuberculosis is fairly often concurrent with this dis-

ease. Painless progressive enlargement of lymph nodes is the chief presenting complaint. Other symptoms are weight loss anorexia fever pruritus cough and dyspnea. Remissions and exacerbations in the early disease are quite unpredictable. The Pel-Ebstein type of fever may occur. Pain is a common later symptom and is often due to bone lesions. The final diagnosis of the disease rests on biopsy. The prognosis is that of inevitable death but this may occur a few weeks after diagnosis or not for many years. Females with the disease are said to live longer than males. The duration of illness is very hard to establish since the actual onset can usually not be determined even within several months. Death is due to generalized visceral invasion, secondary infection, or to destruction of the bone marrow. Terminal anemia is common. Changes in the white blood count are not constant or diagnostic. Marked eosinophilia is rare. Aspiration of the sternal marrow is not a positive diagnostic procedure. Most patients have an elevated sedimentation rate during active stages of the disease. No complement fixation or other serologic test has been devised. Without invasion of the kidney or pressure on the excretory urinary tract urine changes are only those to be expected with any chronic, febrile disease. The elevation of the basal metabolic rate is proportional to the extent and the activity of the disease. Patients with advanced disease fail to react to the tuberculin skin test.

Röntgen radiation is the treatment of choice for localized disease. Some believe this does not influence the duration of life. Radiation must be used with care in the presence of tuberculosis and a depressed bone marrow. Superficial nodes are much more successfully treated than deep ones. Radium is not very useful with this disease. Other radioactive substances have been disappointing. In early cases, radical local excision plus radiation often gives better results than would be expected. Surgery may be necessary to relieve dangerous neurological symptoms due to pressure such as paraplegia. With this exception, some authors believe that surgery is useless and often dangerous. Vaccine and serum therapy have been disappointing. Chemotherapy with the exception of the use of the nitrogen mustards (which are somewhat effective) has also unfortunately been of little or no avail.

There is much argument as to whether Hodgkin's disease is a neoplasm an inflammation a disease midway between these first two or a metabolic disturbance. There is much evidence for either of the first two theories. The fatal termination suggests a neoplasm but the very variable clinical course with its remarkable remissions and exacerbations suggests an inflammation. The histopathologic picture can be argued either way. Perhaps the truth is nearest the view that combines these two opposed theories. Unfortunately this disease does not occur and cannot be produced in laboratory animals. Transmission experiments to animals have also failed in all but a few dubious cases. Many different

bacteria have been isolated from Hodgkin's nodes but this means little since the same bacteria can also usually be obtained from control nodes. Much of the early work in this field is of almost no value because of very inadequate aseptic procedures. Diphtheroids, brucella organisms, and tubercle bacilli have been especially worked with, but many authorities now say that none of these is directly concerned in the etiology of Hodgkin's disease. Gordon discovered an interesting encephalitic reaction in rabbits injected with material from Hodgkin's nodes. There was hope for a time that this might be useful as a diagnostic procedure but this failed when it was found that the same reaction could be elicited with many other types of material than Hodgkin's nodes and was apparently correlated with the concentration of eosinophiles in the material injected. Recently interesting viruslike (?) inclusions have been demonstrated in tissue cultures of normal human lymph nodes grown in a fluid to which has been added a cellfree extract of Hodgkin's nodes.

JAMES WEAVER, M.D.

Hyperthermia in Association with Shock. JAMES L. HANSEN. *Acta chir scand.* 948 p6 530.

The author presents clinical evidence to show the close association between shock and hyperthermia postoperatively in some cases. He suggests that the syndrome can be delimited on a purely clinical basis and should therefore be considered a specific post operative condition.

This investigation extended over a period of 4 months, during which rectal temperatures were measured every hour for the first 24 hours after all operations of any size. Twelve of 20 patients with typical shock revealed no characteristic fluctuations of the temperature but in 7 a rectal temperature of between 39.1 and 40.5° C. (102 and 104° F) was recorded in from 3 to 6 hours after operation. The fever reached its maximum at the time the shock was most pronounced.

Blood samples were taken one to three times during the temperature rise, but the blood cultures were negative and the subsequent course revealed no evidence of infection neither did the postmortem examination in 2 patients who died. After successful treatment of the shock the temperature fell at the same rate at which it rose, from 25 to 0.5 degree per hour.

Typical postoperative shock is often found to be associated with a sudden rise in temperature. It is stressed that the abrupt temperature rise occurs without chills and that the perspiration ceases during the temperature fall. The rise in temperature at tending shock is due to reduced elimination of heat secondary to arteriolar contraction, mainly in the extremities, and the condition occurs when the organism strives to conduct the reduced circulating amounts of blood to the vital centers in the medulla oblongata. The temperature promptly falls after treatment of the shock by blood, plasma, and fluids. Blood cultures, the subsequent clinical course, and

autopsies reveal no evidence of infection or other pathology as the cause of the hyperthermia.

JOHN H. MORGART, M.D.

Pterygium Colli and Allied Conditions. H. O. FORD. *Canad. M. Ass. J.* 948 59 151.

The author presents a case of pterygium colli in a 19 year old patient, with a description of a new surgical procedure for the correction of this deformity.

An incision about 3 inches long is made in the midline posteriorly and the skin is undercut. A second incision about 5 inches long is made transversely at the top of the first incision forming a "T". Each flap of the skin is then raised and pulled upward and inward until the skin folds are obliterated as in operations for the removal of wrinkles. The excess skin is excised to leave a triangular defect. The skin edges are sewn together in the form of a "T". The scar is posterior and well hidden by the hair or collar. Both folds are corrected through one operative field and it is possible to obtain symmetry very easily.

The author then reviewed the literature concerning various cases of pterygium colli, and he states that the condition is rare and widely distributed geographically. It does not appear to be hereditary but has been reported in 2 sisters.

In its simplest form it consists of a bilateral fold of skin arising from the mastoid region but occasionally from in front of the ear and extending to the shoulder. Usually it is thin but it may be thick and can be picked up and stretched to the side of the neck. It consists of skin and subcutaneous tissue although it has been suggested that there may be some abnormality of the platysma myoides. The deep fascia and muscles are not affected. It is possible that there may be some deficiency and loss of tissue but there is no histologic evidence for this. The hairline is low posteriorly giving the appearance of a short wide neck. The cervical vertebrae are normal and there is no impairment in movement. In most instances there is no mental retardation but in some cases the condition suggests mongolism.

Rarely however does it occur as simply as this, but is associated with a wide variety of malformations. Because of this association with these anomalies it is suggested that it is the result of faulty development of the neck and is thus related to Klinefelter's Klippel Feil syndrome and Sprengel's deformity and that the signs of these may overlap. A special subvariety has been described which exhibits the triad of infantilism, webbing of the neck, and cubitus valgus, and occurs in women. However this type has also been reported in a man.

Endocrine deficiency when present, may be regarded as secondary to the underlying congenital defect, and not as the primary cause of the condition. Endocrine therapy has caused some improvement in the genital symptoms.

In most reports there is no mention of treatment of this defect. One author suggests a bloodless orthopedic procedure. The only surgical techniques described were modifications of the "Z" type plastic

operations. General reference was made to other plastic methods without elaboration.

JOHN E. KARABIN, M.D.

Morbidity and Mortality in Talc Granulomas: Report of a Fatal Case. ALVIN J. SWINGLE, *M.D.*
Surg. 1948 128 144.

After a survey of the literature and on the basis of his own observations the author re-emphasizes the incidence of morbidity and postoperative complications in which talc powder has been incriminated as the etiological agent. He records the course of a patient who was operated on 14 times for adhesions and intestinal obstruction between her first and final admissions which terminated in the death of the patient, and gives the autopsy findings.

The clinical and experimental evidence incriminating talc as the etiological agent in the formation of intraperitoneal granulomas and adhesions is reviewed. In addition talc granulomas have been reported in the skin, vagina, rectum, eye, gall bladder, healing surgical wounds, scars, and brain. In the Veterans Hospital, Wood, Wisconsin, Ross has found a large number of granulomatous lesions of the foreign body type among routine surgical specimens definitely identified as talc granulomas.

The commercial talc used on surgical gloves has been found to contain talc (82.7 per cent), calcium carbonate (8.7 per cent) and magnesium carbonate (7.6 per cent). 55 per cent of the particles were less than 5 microns in diameter. The portals of entry have been found to be perforations of gloves which occur in 22.6 per cent of all the gloves used, and rubber drains powdered with talc for autoclaving. Regardless of how thoroughly they are washed, subsequent examination under the polarized microscope will reveal many birefringent crystals still clinging to the rubber.

Since talc powder has been so conclusively demonstrated to be a dangerous agent in surgery, its use should be discontinued. Of the substitutes offered to date, the modified corn starch preparation recommended by Lee and Lehman seems best to fulfill all the requirements of a dusting powder suitable for use on surgical gloves and drains.

JOHN H. MOHARDT, M.D.

Mineral Balance during Brief Starvation. The Effect on Serum Electrolytes and Mineral Balance of Maintaining the Intake of Certain Mineral Constituents. LEROY E. DUCKAN, JR., RICHARD J. MEYER, and JOHN EAGER HOWARD
J. Clin. Invest., 1948 27 350.

Two obese male patients were subjected to two periods each of 4 days of starvation. During one fast, each of the patients received only water. In the other, a salt mixture containing approximately the amounts of sodium, chloride, potassium, and phosphorus of a 1,200 calorie diet was given in addition to the water. Between the two fasting periods both patients were fed a diet containing 1,200 calories for 6 days.

Fig. 1 (Foucar). Pterygium colli or webbed neck, lateral view.

Fig. 2. Posterior view showing folds of skin and low hair line, which give the appearance of shortness to the neck.

Fig. 3. Posterior view showing laxness of the skin.

Fig. 4. Lateral view after operation showing complete obliteration of the fold. Note also the inconspicuous scar posteriorly.

Administration of the salt mixture resulted in no lessening of the nitrogen lost by fasting and effected no alteration in the amount of weight lost. In one patient there appeared to be a considerable saving of potassium from the salt mixture in the other patient none.

On the first day of the fasts, large savings of sodium and chloride were manifest from the salt mixtures, but thereafter excretion of these elements was rapid, and the total amounts of sodium and chloride lost over the 4 days were the same in the fasting periods with and without the salt mixtures.

The sodium, chloride, and potassium of the mixtures were almost completely absorbed, as judged from the quantities of these elements in the stools and by the increased amounts appearing in the urine. There was no appreciable rise in phosphaturia when the salt mixture was given as compared with the fasting alone. In one of the patients there was heightened calciuria and hypercalcemia as a result of the salt mixture.

The concentrations in the serum of sodium, chloride, and potassium were unaltered by the salt administration. Stools were more frequent during fasting when the salt mixture was given, but only minimal amounts of the administered salts were recovered in the stools. WALTER H. NADLER, M.D.

Penicillin, Streptomycin, Dicumarol and Blood Coagulation: Thromboplastic Properties of Penicillin. DAVID L. MACEY. *Souk. M. J.* 1948, 41: 720.

Animal experiments and records of clinical patients show that penicillin shortens the coagulation time and the prothrombin time of whole blood. Some of the four crystalline-active principles of penicillin are more effective in this regard than others. For this reason, amorphous penicillin is more effective in shortening coagulation time than are the newer colorless crystalline preparations. Suitable doses of dicumarol can be used to antagonize the excessive thromboplastic effects arising from intensive penicillin therapy. In experiments on animals the reverse is shown, in that the prolongation of prothrombin time and whole blood coagulation which is produced by dicumarol can be corrected by penicillin. This mutual correction of penicillin and dicumarol enhances their use.

JAMES WEAVER, M.D.

An Italian Precursor to the Study of Penicillin (Un italiano precursore degli studi sulla penicillina). GIUSEPPE PEZZI. *Ann. med. nat. Roma*, 946, 51: 51.

The author states that on page 91 of the first number of the *Annali d'Igiene Sperimentale* for the year 1895 appears an article entitled "On the Extracts of Certain Molds—Researches by Doctor Vincenzo Tiberio." He then gives important quotations from the original article, which bring out the work done by Vincenzo Tiberio on molds. This work was done before Tiberio entered the naval medical service while he was an assistant in the Pathologic Institute and afterward in the Institute of Hygiene of the University of Naples.

The original article is divided into three parts: (1) preparation of the cultures, (2) preparation of aqueous extract with bactericidal power, and (3) the chemotactic power and action of molds in the experimental infections with the typhoid bacillus and Vibrio of cholera.

The conclusions arrived at by Tiberio and quoted by Pezzi are as follows:

"In the cellular substance of molds are contained water-soluble principles which possess a bactericidal action. I do not pretend to state that this action extends to all bacteria. The liquid obtained (from penicillium and aspergillus) is endowed with notable chemotactic powers. This liquid has a preventive and therapeutic action."

Thus, Pezzi states that although the work of Tiberio remained within the limits of the laboratory, the concepts arrived at by him were exact. A brief review is made of different products derived from organisms and used as antibiotics and therefore leading up to streptomycin.

A brief life history of Vincenzo Tiberio follows, showing that he was born on March 1, 1869 and died on January 7, 1915. At the time of his death he was Director of the Cabinet of Hygiene and Bacteriology at the Marine Hospital in Naples.

LUIGI J. FROSTEN, M.D.

The Toxicity of Sodium Alginate in Cats. MAYNARD B. CROFOWETH. *Ann. Surg.* 1948, 127: 173.

An absorbable, hemostatic, and readily manufactured surgical gauze which can be sterilized by autoclaving can be prepared from alginic acid, the product of certain seaweeds. Because of the usefulness of absorbable surgical gauzes, the discovery of a material which, on manufacturing grounds, is as suitable as alginic acid, is very important. The toxicity of commercial sodium alginate was studied by the intraperitoneal or intravenous injection in cats. Solutions of sodium alginate resulted in the production of large antemortem intracardiac clots. The toxicity of alginate gauze was also studied by this author.

As the result of this study of the action of alginic gauzes in the animal body, the material cannot be recommended for surgical use as an absorbable gauze. It would seem that the ability of alginic acid to form gels with calcium, which may or may not be the mechanism underlying its hemostatic action, is sufficient to cause serious localized circulatory embarrassment.

POSTTRAUMATIC VASOMOTOR DISORDERS

With Particular Reference to Late Manifestations and Treatment

HARRIS B. SHUMACKER, JR., M.D., Indianapolis, Indiana, and

DAVID I. ABRAMSON, M.D., Chicago, Illinois

ALTHOUGH generally injury to an extremity is followed by signs and symptoms which are readily explained upon the basis of the trauma sustained and the resultant dysfunction in certain instances there are superimposed other changes which can be accounted for only on the assumption that some reflex disorder has been initiated by the local tissue damage. Such a reflex state has been the subject of gradually increasing study and interest since 1900 when Sudeck first presented the entity of acute atrophy of bone following certain inflammatory processes. The numerous terms¹ which have been utilized to describe this clinical condition bear witness not only to the widespread disturbances which may occur but also to the lack of agreement as to what constitutes the primary characteristic alteration. Since the most constant finding is some type of vasomotor disturbance it is our feeling that the broad term posttraumatic vasomotor disorder is the most appropriate name for this clinical entity.

From the Vascular Center, Mayo General Hospital, Calesburg, Illinois; the Department of Surgery, the Indiana University Medical Center, Indianapolis, Indiana; the Department of Medicine, the University of Illinois College of Medicine; and the Department of Medicine, Michael Reese Hospital, Chicago, Illinois.

Among the names which have been given to the syndrome are the following: Sudeck's trophy, acute trophy of bone, post-traumatic osteoporosis, posttraumatic painful osteoporosis, traumatic ribbitis, peripheral trophoneurosis, reflex nervous dystrophy, reflex sympathetic dystrophy, posttraumatic dystrophy, minor causalgia, traumatic angiospasm, chronic traumatic edema, and posttraumatic edema.

Excluded from such a category are a number of related conditions. Among these are major causalgia and phantom limb pain syndromes with such characteristic features that they are best considered as separate entities. Marked sympathetic overactivity may be present in certain cases of occlusion or division of peripheral arteries associated with trauma. However, in those conditions in which the occluded vessel is of real importance in the nutrition of the extremity, part of the resultant difficulty arises from the direct decrease in local blood flow and hence this type of vasospastic alteration is likewise better separated from the posttraumatic vasomotor disorders. There is also good reason to exclude from this group the vasospastic state which follows cold thermal injuries—frostbite, trench foot and immersion foot—and that which is associated with deep thrombophlebitis. Those vasomotor disturbances which are apparently the sole result of disuse likewise do not belong to the category of posttraumatic vasomotor disorders. Although all of the conditions mentioned have a number of features in common, each possesses certain peculiar characteristics which make it advisable to deal with it as a distinct syndrome.

It is generally accepted that the primary mechanism responsible for posttraumatic vasomotor disorders is some type of reflex disturbance initiated by the local injury and involving in the reflex arc the components of the sympathetic nervous system. Although nu-

Penicillin, Streptomycin, Dicumarol and Blood Coagulation: Thromboplastic Properties of Penicillin. DAVID L. MACINTYRE. *South. M. J.* 1948, 41: 780.

Animal experiments and records of clinical patients show that penicillin shortens the coagulation time and the prothrombin time of whole blood. Some of the four crystalline-active principles of penicillin are more effective in this regard than others. For this reason amorphous penicillin is more effective in shortening coagulation time than are the newer colorless crystalline preparations. Suitable doses of dicumarol can be used to antagonize the excessive thromboplastic effects arising from intensive penicillin therapy. In experiments on animals the reverse is shown in that the prolongation of prothrombin time and whole blood coagulation which is produced by dicumarol can be corrected by penicillin. This mutual correction of penicillin and dicumarol enhances their use.

JAMES WEAVER, M.D.

An Italian Precursor to the Study of Penicillin (Un italiano precursore degli studi sulla penicillina). GIUSEPPE PIZZALI. *Ann. med. nat. Roma*, 946: 5-31.

The author states that on page 91 of the first number of the *Annali di Igiene Sperimentale* for the year 1895 appears an article entitled "On the Extracts of Certain Molds—Researches by Doctor Vincenzo Tiberio." He then gives important quotations from the original article, which bring out the work done by Vincenzo Tiberio on molds. This work was done before Tiberio entered the naval medical service while he was an assistant in the Pathologic Institute and afterward in the Institute of Hygiene of the University of Naples.

The original article is divided into three parts: (1) preparation of the cultures, (2) preparation of aqueous extract with bactericidal power, and (3) the chemotactic power and action of molds in the experimental infections with the typhoid bacillus and Vibrio of cholera.

The conclusions arrived at by Tiberio and quoted by Pizzali are as follows:

"In the cellular substance of molds are contained water soluble principles which possess a bactericidal action. I do not pretend to state that this action extends to all bacteria. The liquid obtained (from penicillium and aspergillus) is endowed with notable chemotactic powers. This liquid has a preventive and therapeutic action."

Thus, Pizzali states that although the work of Tiberio remained within the limits of the laboratory, the concepts arrived at by him were exact. A brief review is made of different products derived from organisms and used as antibiotics and therefore leading up to streptomycin.

A brief life history of Vincenzo Tiberio follows, showing that he was born on March 1, 1869 and died on January 7, 1915. At the time of his death he was Director of the Cabinet of Hygiene and Bacteriology at the Marine Hospital in Naples.

The Toxicity of Sodium Alginate in Cats. MAYNARD B. CROOKWORTH. *Ann. Surg.* 948, 271: 173.

An absorbable, hemostatic, and readily manufactured surgical gauze which can be sterilized by autoclaving can be prepared from alginic acid, the product of certain seaweeds. Because of the usefulness of absorbable surgical gauzes, the discovery of a material which on manufacturing grounds, is as suitable as alginic acid, is very important. The toxicity of commercial sodium alginate was studied by the intraperitoneal or intravenous injection in cats. Solutions of sodium alginate resulted in the production of large antemortem intracardiac clots. The toxicity of alginate gauze was also studied by this author.

As the result of this study of the action of alginic gauzes in the animal body the material cannot be recommended for surgical use as an absorbable gauze. It would seem that the ability of alginic acid to form gels with calcium, which may or may not be the mechanism underlying its hemostatic action, is sufficient to cause serious localized circulatory embarrassment.

C. FRED GOEDEN, M.D.

plaints were explicable solely on the basis of the local tissue injury

The commonest story elicited was that of the development of severe pain in the affected hand or foot shortly after injury associated with swelling coldness, and cyanosis and often excessive sweating. Active use of the hand or foot was impossible because of pain on movement or on weight bearing. A few patients had no significant pain but instead noted evidence of excessive sympathetic activity such as coldness cyanosis and hyperhidrosis. In some edema out of proportion to the injury sustained was the most striking finding while others had increased vasomotor tonus without edema. Marked weakness of the involved limb was almost constantly present.

It is worthy of note that there was nothing in the history or clinical records of these patients to suggest that the early circulatory alterations were those of vasodilatation and increased blood flow as has been described by some investigators (11) and as we have observed in some of our civilian patients. Indeed the prominent initial findings were those of sympathetic overactivity.

EARLY TREATMENT

In the majority of the patients no active effort was made during the first few weeks after injury to treat anything but the local lesion. Wounds were properly debrided and foreign bodies were excised when deemed advisable. Fractures were immobilized in plaster. Very few patients were treated by casts in whom there was no fracture or other specific indication for such therapy. Warm compresses locally and sulfonamides by mouth or penicillin parenterally were used to combat infection.

When it became apparent that some profound vasomotor disturbance was superimposed upon the local injury, other methods of treatment were instituted. Those most commonly utilized were contrast warm and cold baths, Buerger's exercises, whirlpool baths, massage and local heat. Little serious effort was made to establish early active motion and weight bearing. In only 2 patients were sympathetic blocks employed during the first

month of the difficulty. One of these underwent continued improvement after 2 blocks carried out during the second week following the injury. When examined several months later he demonstrated few sequelae. The other patient derived transient benefit from a single block performed on the day of injury and significant lasting improvement from several blocks done 5 months later.

LATE MANIFESTATIONS

An average of 5 3 months had elapsed between the initial injury and the time of admission of the patients to the Mayo General Hospital. In the interval the correct diagnosis had usually been established although some cases were still considered examples of deep venous thrombosis, thromboangitis obliterans, or other primary vascular disorder.

In Table I are listed the chief complaints elicited on admission and the physical findings noted upon examination. Pain, edema, coldness and cyanosis were the commonest symptoms. Nearly one-fifth of the patients had sensitivity of the affected part to cold and in a few this disturbance was very severe. Other individuals complained of stiffness, numbness or chronic ulceration. Pain was primarily experienced on weight bearing or other activity. Though commonly described as an aching sensation it was throbbing in character in some patients and burning in others. It prevented normal physical activity in most instances and its long duration had generally completely destroyed confidence in the ability to use the affected limb properly. Only 2 patients had moderate burning pain at rest which differed from true major causalgia in its inconstancy. Some individuals complained of massive swelling but most of them of only mild or moderate edema.

Upon admission 21 of the 111 patients with difficulties involving the lower extremities were confined to bed, 32 were ambulatory with the use of crutches, 16 with canes, and 42 walked without aid but with a definite limp. Those with involvement of the upper extremities tended to guard the affected limb and to avoid using it.

Examination revealed motor weakness of the affected limb in every instance amount

merous ingenious theories have been postulated no definite proof has been obtained to verify the correctness of any of them. They are discussed in other reports (1, 2, 7, 8, 10, 11) and to review them here would be profitless. Similarly no agreement has been reached as to the real cause of the osteoporosis which so commonly occurs (3).

The purpose of the present communication is to call attention to the clinical manifestations of posttraumatic vasomotor disorders as observed in a large series of cases and to discuss the merits and limitations of various therapeutic procedures. It is hoped that analysis of such a group will be useful in pointing out the heterogeneous disturbances found in this condition and the variety of measures which have an important place in its treatment.

CLINICAL MATERIAL

A study of 142 male patients with post-traumatic vasomotor disorders, involving 143 limbs forms the basis for this report. All were soldiers admitted to the vascular center of the Mayo General Hospital after having first been treated in other army installations. The information concerning initial manifestations and early therapy is subject therefore to the criticism that it had been collected by other observers. However every effort was made to reconstruct the sequence of events and the results of early treatment through a careful perusal of the previous clinical records and through questioning the patients in detail with regard to the early phase of the disease. The data concerning late manifestations and the results of late treatment are based upon close personal observation during the period of hospitalization.

The subjects varied in age from 20 to 38 years, with an average of 27 years. Twenty-five had had a tendency to coldness of the hands or feet prior to the present difficulty and an equal number had noted in the past varying degrees of hyperhidrosis in the limbs. A history of previous injury to the affected limb was obtained in 5 individuals, and of frostbite or trench foot in 4. Eighty used tobacco. There was no definitely relevant family history in any of the patients, although such vascular difficulties as varicose veins, vascular

thrombosis or hemorrhage had occurred in the families of 12.

The disorder became manifest after soft tissue wounds in 58 patients after sprains in 19 and after crushing or other external injuries in 11. In 14 it followed compound fractures of small bones, and in 7 simple fractures of small bones. In 24 it resulted from compound fractures of long bones, and in 5 from simple fractures of long bones. In 3 it was the consequence of infection while in 1 the surgical removal of a small cyst was the initiating cause. Besides the precipitating injury 19 of the patients had associated nerve paralysis and 4 had sustained laceration of a minor artery. One individual incurred a mild frostbite at the time of injury. In all cases but 1 the disorder began during army service.

In 111 patients a foot was affected and in 31 a hand. In the case of 1 soldier injuries to an upper and lower extremity were followed by vasomotor disturbances in the corresponding hand and foot. Not infrequently in patients who had no previous tendency to coldness of hands or feet, evidence of increased vasomotor tone now was present not only in the injured limb but to a lesser extent in the contralateral one or sometimes in all four. In such instances the symptoms were generally not marked in the uninjured extremity although 1 subject developed such severe cold sensitivity in both hands following injury to the left forearm as to require bilateral dorsal sympathectomy.

EARLY MANIFESTATIONS

The prominent initial symptoms and signs, obtained from a study of the early clinical records and from questioning the patients, were as follows: pain in 97 patients, swelling of the affected hand or foot in 95, cyanosis in 93, coldness in 72, hyperhidrosis in 52, numbness in 26 and pallor in 3. The symptoms were generally noticed within a period of from several days to a few weeks after injury. However in some individuals, whose initial trauma required immobilization of the limb in plaster signs and symptoms suggestive of a posttraumatic vasomotor disturbance became evident only when the cast was removed and the patient became ambulatory the preceding com-

perature or sweating. Still others showed extreme local reduction in temperature or hyperhidrosis or both without significant edema or cyanosis.

In a number of cases reflex vasodilatation by means of body warming was carried out. In all instances but 2 the rate of rise in skin temperature was a parallel in the affected and normal extremity. In the 2 exceptions a lag was noted in the injured limb. In all instances however there was no difference in the ultimate height of rise of temperature in the injured extremity as contrasted with the normal one despite lower initial control skin temperature readings in the involved limb. In several cases the reactive hyperemia test was performed and uniformly the results in the affected limbs were normal except for a delay in the appearance of the flush in 1 instance.

Records of roentgenological examination of the hands or feet were available for study in 51 cases. In 42 there was evidence of generalized or spotty osteoporosis while in the 9 remaining no abnormalities were noted. The change was minimal in 6 cases, moderate in 28 and marked in 8.

Most of the patients had assumed the attitude and behavior of the chronic invalid. They were weary from prolonged disability and hospitalization and usually had a relatively hopeless viewpoint toward the possibility of eventual recovery. In some the concept seemed to be fixed that the condition from which they suffered was sufficiently disabling so that they could look forward to separation from the Service. In only 11 individuals however was a neuropsychiatric disorder diagnosed by psychiatric consultants. In the latter the general attitude and behavior were often no different from those of the group as a whole except that a few showed evidence of anxiety. They all demonstrated however certain local findings which were helpful in segregating them from the other patients. The most common observation of this sort was a forced effort in response to a request to perform a certain movement. This was associated with a gross tremor or with little or no movement of the part but with obvious contraction not only of the muscles

ordinarily utilized but of their antagonists as well. For example if a patient were attempting to extend his foot it was often apparent that both the extensors and the flexors were being brought into a state of tonic contracture so that no movement occurred except possibly a coarse tremor. This sign more than any other was helpful in establishing the presence of a definite psychomotor block.

LATE TREATMENT

The type of late treatment given and the results obtained will be considered under 4 categories namely active exercise and physical therapy, neuropsychiatric treatment, lumbar sympathetic block, and lumbar sympathectomy. The effect of treatment upon osteoporosis will be considered separately. It is realized that these divisions are somewhat arbitrary and overlap. For example whether or not a neuropsychiatric disorder was present and regardless of whether expert psychiatric therapy was required it was felt necessary to gain the confidence of the patient and to impress upon him both the necessity for his active co-operation and the favorable outlook that might be expected. Such instructions and suggestions on the part of the attending physician in reality constituted psychiatric treatment. Again active use of the involved extremity was part of the routine no matter what other type of therapy was carried out. It was learned early in the treatment of post-traumatic vasospastic states that little could be accomplished from psychiatric interviews, sympathetic blocks or sympathectomy if the patient was not urged repeatedly to take advantage of any resulting improvement in his condition by following up this gain with persistent use of the affected limb. It was only in this manner that the atrophy, weakness, stiffness, and improper stance or gait were ultimately corrected.

Patients Treated Primarily by Active Exercise and Physical Therapy

In 95 individuals active use of the involved extremity constituted the chief medical therapy. When the patients were first seen the importance of such a step was emphasized and explained to them in terms which they could

TABLE 1.—LATE SYMPTOMS AND SIGNS IN POST-TRAUMATIC VASOMOTOR DISORDERS

Chief complaint about 3 months after injury		No. of patients
Pain		27

Temperature of the affected limb was lower than normal		3
Temperature of the affected limb was higher than normal		3
Temperature of the affected limb was equal to normal		3

ing in several to virtual paralysis. Muscle atrophy was commonly evident and stiffness of the joints, not infrequently. Hyposthesia was occasionally present only at times associated with a definite sensory nerve injury. Approximately one half of the patients showed varying degrees of edema. In most of them the swelling was mild or moderate but in some it was massive even after prolonged bed rest. In a few it was present despite elevation of the extremity. Cyanosis was observed in the majority of cases in some in the horizontal position but in others, only in dependency. Rubor and pallor were uncommonly noted. Varying degrees of hyperhidrosis were often present in some the sweat literally ran off the involved hand or foot. The affected hand or

foot was generally cool or cold. In 80 patients it was cooler than the contralateral uninjured one. In some the difference in temperature was great while in others it was only slight especially when the normal limb was itself excessively cool. The temperature of the affected normal and normal extremity was approximately equal in 40 patients, in all of whom both limbs tended to be cool or cold. In some of these individuals the affected limb cooled more rapidly than the other upon exposure to a cold environment. In the 22 remaining patients the involved hand or foot was warmer than its mate. In 2 of these there was an abnormally high skin temperature as a result of existing infection while in the 21 others the thermocouple readings of the affected part were at the lower level of the normal range or even cooler.

In 88 patients both oscillometric and skin temperature studies were made (Table 1). Oscillometry was found to be comparatively reduced in the affected extremity in 59 and skin temperature in 44. Both sets of readings were definitely lower in the involved limb however in only 32. Only in 14 patients was no significant difference noted in either oscillometric and skin temperature of the affected and normal extremities and only in 3 patients were both oscillometric and temperature values greater on the affected side. In 2 of the latter cases there was a definite peroneal nerve paralysis in addition to the posttraumatic disorder and though somewhat warmer than the opposite mate the affected foot in these 3 cases was actually not abnormally warm but rather of normal temperature or somewhat cooler than normal.

It was a striking observation that although all patients showed evidence of some vasomotor alteration and although many had edema cyanosis coldness, and hyperhidrosis, a considerable number of them exhibited one of these changes out of proportion to the others. For example some individuals had intense cyanosis without much edema, coldness or increased sweating. Others had massive edema and minimal changes in color tem-

1. The majority of patients accurate thermocouple studies of skin temperature were carried out and in the remainder temperature judged by palpation alone.

sary to impress upon all the patients the fact that they could accomplish much more by their exercising at frequent intervals throughout the day than by relying solely on the relatively short period of treatment given by the physical therapist. The same type of program was carried out in the case of the individuals suffering from involvement of the hands.

As improvement took place the patients as a rule underwent a change in attitude and became more optimistic concerning the outcome of their disability. Concomitantly with this altered state of mind they appeared to pursue the program more vigorously and to improve more rapidly. As a result the edema diminished (Fig. 1 a and b) and the gait became relatively normal. If discomfort was still present it was less severe, appearing only after the patient had walked for a distance of from 1 to 3 or more miles. At the same time there were noted an increase in muscle power and an alleviation of the vasomotor disturbance. Almost invariably the affected limbs which had been cold, wet and cyanotic on admission gradually became warmer, drier and better colored.

It is of interest to discuss in detail the results in one of the patients in this group.

This individual entered the hospital complaining of marked swelling, pain, coldness and hyperhidrosis of the right hand and the inability to use the fingers. He had sustained a fracture of the bones of the right forearm on a number of occasions previous to the onset of his symptoms. When the hand was first examined it showed marked edema and stiffness of all the fingers (Fig. 2 a). The patient was given an ordinary tight surgical glove to wear and was encouraged to use the fingers as much as possible. At the same time an intensive course of physical therapy was instituted and the patient was given a soft rubber ball which he kept squeezing most of the day. At the end of 2 weeks of this regimen the edema had completely disappeared and the patient was able to move the fingers of the right hand almost as well as those of the left (Fig. 2 b).

A satisfactory result followed active exercise and physical therapy in 50 of the 95 cases. Five other individuals were under observation too short a time to permit final evaluation of the treatment. In the 40 remaining patients little if any beneficial effects were noticed. In some respects many of the cases considered in the subsequent 3 sections also represent fail-

ures with this method of treatment, since all but a few had an adequate trial of active exercise and physical therapy prior to the institution of the other procedures.

Patients Treated Primarily by Neuro-psychiatric Means

In 11 individuals definite evidence of some neuropsychiatric disorder was confirmed by psychiatric consultation, although in one of these there was a difference of opinion. This individual made fair progress with active exercise of the affected upper extremity alone, but then improvement reached a plateau following which there were still some residual cyanosis, increased sweating and weakness. The complaints of a second patient thought by the psychiatrist to be largely psychosomatic cleared so satisfactorily with ordinary physical

Fig. 1. Sublease of edema, then a return and physical therapy. Left: Edema of right foot upon admission; 1 day, 1 month after trivial injury in which small nail fragment penetrated the ankle proximal to the internal malleolus. Right: Appearance of foot 1 year after return to normal. Elastic support was used during the demarcation of the lung area now to appear.

comprehend. The role that disuse was playing in their condition was stressed, and the fact was emphasized that a vicious cycle had been set up which would result in continued difficulty so long as inactivity persisted.

In those individuals who had demonstrable edema of an extremity, care was taken to attempt to bring this under control before doing anything else. Such patients were put to bed with the extremity elevated until all swelling had disappeared. If this then recurred with activity, elastic support was utilized together with periods of rest in bed with the limb elevated. An attempt was made to avoid the return of the edema by limiting activity to a little less than that necessary to cause its appearance. The use of elastic support was continued until swelling was no longer produced by dependency.

In the case of the individuals confined to bed on admission, the therapeutic program was aimed at making them ambulatory as rapidly as the circumstances permitted. This sometimes involved a short period with the use of crutches and then a cane before unaided walking could be accomplished. At times widespread petechial hemorrhages appeared in the skin of the extremity when the patient first began to walk after a prolonged period of immobilization of the limb. This response usually cleared up within a short period of

time as activity was increased. If patients were admitted using crutches or canes, an attempt was made to have these discarded immediately. Since on first beginning to walk, they generally did so timidly, favoring the affected limb, careful attention was paid early in the reconditioning program to the acquisition of a normal stance and gait. At times this accomplishment was difficult since most individuals tended to judge improvement by the distance they could cover rather than by the correctness of their gait. However, they were made to understand that more benefit was derived from walking a short distance properly than a long distance improperly. Emphasis was placed on the fact that only through the use of a correct gait would all the muscles be brought normally into play and thus undergo strengthening and improvement in tone.

In addition to active use of the limb, which was the primary type of physical therapy utilized, considerable benefit was obtained through gentle massage and directed active and resisted exercise of all the weak muscles. Passive exercise and manipulation were found to be of little help. In some instances whirlpool baths were utilized, but in general no improvement could be observed from this procedure and hence it was omitted in the treatment of the majority of cases. It was neces-

sary to impress upon all the patients the fact that they could accomplish much more by their exercising at frequent intervals throughout the day than by relying solely on the relatively short period of treatment given by the physical therapist. The same type of program was carried out in the case of the individuals suffering from involvement of the hands.

As improvement took place the patients as a rule underwent a change in attitude and became more optimistic concerning the outcome of their disability. TABLE II.—EFFECT OF SYMPATHETOMY IN PATIENTS WITH PERSISTENT EDEMA

Case	Operation, months after injury	Extremity involved	Original injury	Manifestations	Results
		LL	Compound fracture tibia and fibula	Massive edema, leg. Disrupted tibia, C aneurysm. Small ulcer (At trochant at bone graft abandoned because of edema)	Edema considerably reduced. In casted lower graft. Foot warm, dry well colored.
		RL	Simple fracture, second and third metatarsal and cuneiform	Marked edema, foot and leg, even with bed rest. Cyanosis, coldness, hyperhidrosis, moderate hyperthermia. Pain on weight bearing requires crutches.	Edema largely gone. Foot warm, dry well colored. Some pain on weight bearing after walking. Hyperhidrosis improved.
		LL	Foot crushed	Massive edema, foot and leg, persisting with bed rest, venous and lymphatic stasis. Coldness, hyperhidrosis, hyperthermia, moderate paralysis. Pain on weight bearing. (Conversion hysteria, unaffected by psychotherapy)	Reduction of 1 1/2 in circumference of foot and 1 1/2 in circumference of leg within 4 days. Edema largely subsided. Foot warm, dry. Hyperthermia improved. Motor power improved slightly. Could walk with cane fairly well.
		LL	Soft tissue wound, foot	Massive edema, foot and leg, even with bed rest, elevation, and long courses of penicillin and sulfadiazine. Moderate rest pain. Severe local infection with increased local heat.	Reduction of 1 1/2 in circumference of foot and 1 1/2 in circumference of leg within 24 hours. Edema disappeared but subsequently returned with flare-up of infection, again to disappear with elevation. It has not returned. Pain gone after healing. Walk well.
5		RL	Compound fracture tibia and fibula	Massive edema, severe osteomyelitis, stable	Edema markedly improved. Outcome unsettled.
6		LL	Foot crushed	Massive edema, foot and ankle, persisting with bed rest. Coldness, hyperhidrosis, cyanosis, d hyperthermia. Moderate paralysis. Atrophy. Pain on weight bearing. Bed patient.	Marked improvement. Edema gone except slight after long standing. Sensation normal. Strength much improved. Foot warm, dry well colored. Slight pain after walking mile.
7	5	LL	Soft tissue wound	Marked edema, foot and ankle. Pain on weight bearing requires cane. Cyanosis. Foot warmer and well sensory better than on normal side. Weakness and atrophy. Tibial nerve paralysis.	Steady improvement, and finally no symptoms.
8		LL	Compound fracture phalanx	Moderate edema. Pain on weight bearing causes limp. Cyanosis, hyperhidrosis. Weakness. (Subsequently found to be hysteria)	Little improvement. Some swelling and limp still present. Foot warm and dry.

activity that no psychiatric treatment was necessary. His complaints of cyanosis, coldness, swelling, and pain in the foot on weight bearing subsided slowly but steadily, and when he was transferred to a convalescent facility for advanced reconditioning he had no difficulty save for aching in his foot after walking a distance of 3 miles. The 9 remaining patients were treated either by the psychiatrist or in 1 instance by the ward physician under the direction of the psychiatrist. In most cases the procedures consisted of suggestive therapy under amytal narcosis or hypnosis. In all instances, careful and concerted efforts were made to give the patient insight into his condition and to make him understand that he had no organic disorder which would prevent his recovery provided

he continued to push himself to the limit in the active use of the affected limb.

In 4 patients the results with psychotherapy were good in 1 fair and in 4 poor. Two of those in whom no benefit with treatment was obtained were transferred to a neuropsychiatric center for more intensive therapy.

One of them was a patient who had complained of swelling, hyperhidrosis, and cyanosis of the feet following compound fracture of the proximal phalanx of a toe resulting from an accidentally self-inflicted wound 9 months prior to admission. His symptoms had not improved with activity but he did obtain a reduction in swelling following a lumbar sympathectomy (Case 8 Table II). In fact he made considerable progress but after returning from a convalescent furlough he still had some swelling and weakness of the foot. It was the psychiatrist's opinion that he had definite hysteria since improved strength in the foot and more normal walking could

be demonstrated under hypnosis. Several subsequent treatments were given but the final result was poor.

The second patient had also been admitted with swelling, cyanosis, weakness and pain in the foot on weight bearing. He had improved considerably with active exercise and physical and occupational therapy, but following a convalescent furlough he complained of increased weakness and pain and in addition nervousness, anorexia and insomnia. He had also developed a tremor and some weakness in one of his hands. The psychiatrist felt that he had a definite anxiety state and securing no improvement with amylal narcosis and other treatment recommended his transfer to another hospital.

Of the 2 remaining patients in whom an unsatisfactory result was obtained, one is of interest. In this case, although there was definite evidence of hysteria, no effect was noted from psychiatric treatment. Subsequently, however, considerable though incomplete improvement occurred after sympathectomy (Case 3, Table II).

Of the 4 cases in which the results were considered to be good, 2 will be described briefly.

One was a patient who was admitted to the hospital 4 months after an injury to his right leg sustained when he was kicked during a football game. He had a history of previous trauma to the same limb 1 year before this had been followed by pain, swelling and cyanosis which decreased slowly and finally disappeared. Within a few days after his recent injury he noted a return of these symptoms. They increased in severity so that he could walk only with the use of crutches. He had received a series of 10 sympathetic blocks with some transient improvement in the strength of the affected foot. On examination of the patient it was evident that he was unwilling to do very much for himself. He appeared apprehensive and was rather jumpy while being questioned. He exhibited apparent marked paresis of all the movements of the foot and ankle, but such efforts were associated with tremor and with tonic contractions of antagonistic muscles. The psychiatrist felt that this patient had hysteria and gave suggestive therapy under amylal narcosis. During this procedure the foot which had been cold, wet and markedly cyanotic, became warm, dry and of good color. The patient could move it freely and strongly through a full range of motion. He was made to walk and did so with practically a normal gait. After this single treatment and following further explanation regarding the nature of his progress, he made daily improvement. When he was discharged after a month's hospitalization, his foot was normal in color and warmth, had no swelling, showed only slight reduction in motor power and had a normal

range of action. The patient had no pain except after walking a mile and a half. There was no improvement in the moderate osteoporosis which was present on admission.

The second patient was admitted to the hospital 4 months following shell fragment soft tissue injuries to his left thigh and leg. There had been immediate paralysis and numbness of the foot with return of flexion and of sensation on the sole 6 weeks later. Upon admission the patient complained of swelling, cyanosis, coldness and sweating of the left foot and tingling and aching pain on attempted weight bearing. He walked with crutches. Examination showed cyanosis of the foot, reduction in skin temperature, moderate hyperhidrosis, marked paresis of eversion and complete loss of extension of the foot and toes. There was some hypesthesia of the foot with anesthesia in the distribution of the saphenous and the lateral sural nerves. The neurosurgeon had no doubt that the patient had a sciatic nerve injury with partial peroneal paralysis. Efforts at active use of the limb with a foot-drop brace were futile and since a fairly good response was obtained with a sympathetic block, a lumbar sympathectomy was performed (Case 2, Table III). Following this procedure the patient showed definite improvement and bore weight with the use of crutches. He discarded these for a cane after 1 week. The foot was warm and dry and there was only minimal edema in the leg and none in the foot. Less pain was present on walking. Two months later the sciatic nerve was explored and was found to respond well to faradic stimulation. A week after operation a psychiatric consultation established a diagnosis of hysteria. Following a single amylal interview the patient regained all movements, had a return of sensation and walked unaided normally and without pain.

This case illustrates most emphatically the necessity for keeping in mind the possibility of a psychiatric basis for such complaints and of instituting the proper therapy before attempting other more heroic procedures.

Patients Treated by Sympathetic Block

Thirty two patients had received sympathetic blocks prior to their admission to the Mayo General Hospital. This procedure had been carried out on an average of 6 months after the onset of the disorder with a range of from 1 to 22 months. From 1 to 28 blocks had been given to each individual. Upon analyzing the results of these efforts from the notes in the medical records and from questioning the patients, it appeared that 12 patients noticed no change except in some temporary elimination of coldness, cyanosis, and sweating during the period of anesthesia while

in 13 there appeared to be definite but transient benefit from the procedure. In 4 there was evidence that slight or moderate permanent improvement had resulted and in 3 good permanent results were obtained.

In assaying the value of sympathetic blocks from this material it must be recognized that in a few instances effective anesthesia of the sympathetics had not been achieved as was evidenced by the fact that the foot or hand remained cold and wet following the injection. In others the possible therapeutic effect upon walking was compromised by associated inadvertent blocking of somatic nerves resulting in temporary anesthesia and paralysis, which prevented the use of the lower extremities during the period of effective sympathetic block. Furthermore in most of the patients it was apparent that no effort had been made to have the patient walk or otherwise actively exercise his affected limb immediately after the injection. In addition in very few of the individuals who noted some benefit over a period of hours or days following the procedure was advantage taken of this improvement by insistence upon progressively increasing the use of the limb. There is no question that if sympathetic blocks are to achieve the maximum benefit the involved extremity should be subjected to weight bearing and walking or other active exercise immediately after the injection, and that this should be continued to the point of tolerance. Only by such a plan can the effectiveness of the procedure be properly evaluated.

When the patients came under our care a number of them received sympathetic blocks, but these were done primarily as a preliminary procedure to determine the advisability of sympathectomy. However in 7 individuals the blocks acted as a therapeutic measure. Two of them had a syndrome characterized by coldness, hyperhidrosis, and weakness of a hand, one had rather marked edema of the hand without any other significant changes, while the 4 others demonstrated edema, coldness, cyanosis, and hyperhidrosis of the affected foot. The treatment was instituted from 6 to 12 months following injury. Three of the patients received only a single sympathetic injection and 4 were given 2 treatments.

All of them had a definite steady improvement following the blocks, such as marked diminution in coldness, hyperhidrosis, and edema, return of good color and improved motor power and function. Each individual had previously been making a definite effort to use the extremity actively to the best of his ability but without any apparent improvement and there was little doubt from the sequence of events that the block rather than the other therapeutic efforts was primarily responsible for the altered clinical picture. It is of interest that pain was not a prominent complaint in any of the patients who underwent lasting improvement as a result of sympathetic blocks.

Patients Treated by Sympathectomy

Thirty five sympathectomies were performed upon 34 individuals. Three of them have been included in the section on "Patients Treated Primarily by Neuropsychiatric Means" but are again analyzed here for the sake of completeness. Lumbar sympathectomy was carried out under spinal anesthesia through an anterior extraperitoneal approach; the second and third lumbar sympathetic ganglia, with the intervening chain were excised. Sympathectomy of the upper extremity was performed through a posterior muscle-splitting incision with resection of a portion of the third rib and the transverse process. The second and third thoracic ganglia were decentralized; the chain severed between the third and fourth ganglia, and the isolated segment was encased in a silk cylinder. This was accompanied by intradural section of the second and third anterior nerve roots and extradural section of the corresponding posterior roots. No complications occurred in any of the patients.

Decision to perform the operation rested upon a number of factors. In the case of patients with ulcers, surgical intervention was based primarily upon the chronicity of these lesions and the presence of associated vasospasm. Sympathetic procaine anesthesia proved a reliable test for judging the result which could be expected from sympathectomy in those individuals with evidence of excessive sympathetic activity. Where edema was present, the response with procaine block was

variable. In a very few patients a demonstrable transient diminution in swelling was evident following the block, while in a number of others it was necessary to determine whether the increase in the size of the extremity occurring during a period of an hour's walking immediately following the injection was less than that observed during a comparable interval on another occasion. In most of the patients with edema, however, no convincing evidence could be derived from sympathetic blocks as to whether or not a good result would be obtained from sympathectomy. Nevertheless the therapeutic effect of sympathectomy was frequently satisfactory in these individuals.

Where pain was the primary indication, the study during sympathetic anesthesia likewise yielded variable results. In some cases as soon as the injection had been completed the patient was surprised to find that he could move the affected part freely through a wide range of motion without pain. Furthermore he could walk or otherwise exercise the extremity with either no pain or with much less discomfort than was present previously. In such instances there appeared to be good evidence that sympathectomy would be effective. In others, however, sympathetic anesthesia had no beneficial effect upon the pain associated with exercise, and again in them a much better result frequently followed sympathectomy than would have been predicted from the preliminary studies.

For the purpose of analysis the patients subjected to sympathectomy have been divided into 4 groups according to the primary indication for operation, namely those with considerable persistent edema, those with pain on walking, those with evidence of excessive sympathetic activity, and those with chronic skin ulceration. This division is somewhat arbitrary in the sense that rarely were symptoms limited to any one of the categories. For example, some of the patients with edema likewise had pain on weight bearing and evidence of vasoconstriction, while in the case of those whose chief complaint was pain on weight bearing, such findings as excessive vasomotor tonus and slight or moderate edema were also present. Similarly, the individuals

with chronic ulceration had evidence of increased sympathetic activity, edema and discomfort on walking. It is felt, however, that this division serves a useful purpose in presenting the results in a more concise fashion.

In Table II are summarized the data upon 8 patients who were operated upon primarily because of persistence of edema. The procedure was carried out from 4 to 11 months following injury, with an average of 5.0 months. In 1 individual the edema was only moderate and in 1 it was marked and in the 6 remaining it was massive. All of the patients had had a trial of bed rest with elevation of the affected limb and of elastic support on becoming ambulatory. In 6 individuals the edema persisted with bed rest alone and in 4 of these subsidence had not occurred even with a prolonged period of elevation. There was evidence of vasospasm in 6 and in 1 in whom infection was present there was definite local hyperemia (Case 4).

In 1 of the patients in the group (Case 1) in whom swelling was associated with an united fracture of the tibia, exploration for a bone graft had been carried out, but the procedure was abandoned because of the marked water logging of all the tissues. There was considerable reduction in the edema following sympathectomy and when the bone graft was subsequently undertaken, the operator judged that the condition had improved by about 60 per cent. Another patient with extreme swelling (Case 5) associated with a compound fracture and osteomyelitis of the ankle had only slight improvement after operation.

A third individual with edema requires brief discussion.

He was a patient who had sustained a soft tissue shell fragment injury of his left foot (Case 4). The foot and leg were enormously swollen and local infection was present (Fig. 3, a and b) associated with fever and weight loss. Intensive treatment consisting of repeated débridement and incisions and drainage, prolonged sulfonamide and penicillin therapy, and immobilization and elevation of the limb had brought about no improvement whatsoever. A sympathetic block caused no demonstrable diminution of the edema but effected a transient subsidence of pain. Sympathectomy was performed 5 months after the injury and within 36 hours the circumference of the foot had been reduced by 1½ inches and that of the leg by 4½ inches. Within the next few

Fig. 3. Subsidence of edema and healing of ulcer following sympathectomy. a, b, Massive edema of left foot and leg in patient with a posttraumatic vasomotor disorder and infection, resistant to treatment. No improvement

derived from continued bed rest, elevation of the extremity and sulfonamide and penicillin therapy. c, End result following sympathectomy. The ulcer has healed and there is no edema.

days the edema cleared up completely as did the infection and healing occurred so that only a tiny ulcer remained. The patient subsequently had a reactivation of his infection with a transient recurrence of swelling. This however responded well to elevation and rest following which the wound healed completely (Fig. 3 c) the edema disappeared entirely and the patient could walk normally and with comfort.

The 5 remaining cases in the group with edema presented other signs and symptoms more commonly seen following injury. An inability to bear weight properly because of pain was present in 4 while the remaining patient walked with a decided limp. All complained of weakness, 1 had virtual paralysis, and 3 demonstrated hypesthesia. Three of the 5 had signs of intense sympathetic hyper-tonus, with coldness and hyperhidrosis. A fourth had persistent hyperhidrosis and cyanosis and the fifth had a cool foot which however was warmer and demonstrated greater oscillations than the contralateral normal limb. Three of these patients showed either complete or partial subsidence of edema following sympathectomy (Cases 2, 6 and 7). They could now walk better and without discomfort for a greater distance than before operation. The hypesthesia was improved or was no

longer present. One of these individuals (Case 7) was observed for some months, and no signs of swelling recurred during this period. The 2 remaining patients have been mentioned previously. One had some transient improvement in the edema following sympathectomy but was eventually recognized to have a conversion hysteria which responded poorly to psychotherapy (Case 8). The other case is instructive because it illustrates the therapeutic effect of sympathectomy in a hysterical individual who also showed a poor response to psychotherapy (Case 3).

Following a crushing injury of the left foot he had marked swelling, coldness, hyperhidrosis, and hypesthesia (Fig. 4, a). There was almost complete paralysis. No improvement was noted following interviews with the psychiatrist and no effect was observed with a sympathetic block other than transient warmth and dryness of the foot. Eleven months after his injury sympathectomy was performed. The edema which had persisted with bed rest and elevation virtually disappeared within 48 hours after operation. The individual was converted from a bedridden to an ambulatory patient (Fig. 4, b) although he walked with a limp and required a foot-drop brace and a cane. Further psychotherapy was found to be of no avail and since a plateau had been reached he was separated from the service.

Fig. 4. Subsidence of edema following sympathectomy. a, Left. Edema of left foot in a patient with hysteria and a posttraumatic vasomotor disorder of 11 months duration taken after 3 weeks of continuous bed rest with elevation of the extremity. Poor response followed psych therapy. b, Appearance of foot 10 days after lumbar sympathectomy. Edema has almost completely disappeared.

In Table III are summarized results of sympathectomy in 10 patients who complained of pain on weight bearing and in 2 who had pain at rest. At the time of operation 1 had been confined to bed and refused to become ambulatory. 5 walked with the aid of crutches and 2 with canes. The 4 remaining walked with a limp and favored the injured limb. Nine had definite evidence of intense vasospasm and cyanosis was present in all 12. Nine had slight or moderate edema.

The results with sympathectomy were excellent in most of the patients who had pain on weight bearing. One of these individuals who had moderate improvement after sympathectomy has already been mentioned. He was subsequently found to have hysteria and obtained a complete cure after one amygdalotomy (Case 2). Of the remaining patients some were now able to walk several miles before the onset of discomfort while in others there was no residual pain at all. The 2 individuals who had burning rest pain also showed definite improvement in this complaint. In the group as a whole edema either disappeared or was now present only in a slight degree even after prolonged dependency. All of the individuals had warm dry feet and only 1 showed some residual cyanosis. Muscle strength improved and by the time the patients left the hospital there was

an increase in the size of the muscles in several instances where definite atrophy had previously existed. It must be pointed out that except for a few of the early cases the patients in this group had been subjected to a rigid regimen of active exercise prior to operation but with no definite relief in symptoms. Even the several patients who followed no planned program of calisthenics had been encouraged to walk and exercise their affected limb.

In Table IV are summarized the results of sympathectomy in patients with excessive sympathetic activity. Thirteen operations were done upon 12 individuals. Eight were dorsal and 5 were lumbar sympathectomies. Ten of the patients had previously complained of excessive coldness generally associated with both cyanosis and hyperhidrosis under ordinary environmental temperatures and 6 had definite cold sensitivity manifested by marked coldness, stiffness, and discomfort on exposure to a low temperature. The 5 patients with involvement of the lower extremity all had slight or moderate edema and 1 of them also had pain on weight bearing. One of the individuals who had an amputation of a finger had moderate phantom limb symptoms (Case 7).

Complete relief occurred following operation in 7 patients while the 5 remaining were much improved. In each instance in which it

TABLE III.—EFFECT OF SYMPATHECTOMY IN PATIENTS WITH PAIN ON WEIGHT BEARING OR ON REST

Case	Operation, tissues affected	Extremity involved	Original injury	Manifestations	Results
1		LL	Foot crushed	Pain on weight bearing requiring crutches. Marked coldness, cyanosis, hyperhidrosis, moderate edema. Atrophy calf	Walks without limp and only slight pain after prolonged walking. Feet warm, dry well colored
		LL	Soft tissue wound, thigh	Pain on weight bearing requiring crutches, coldness, cyanosis, hyperhidrosis, slight edema. Apparent peroneal palsy; atrophy calf	Moderate improvement in pain. Walks with cane. Feet warm, dry well colored. Subsequently found to have lysis of Complete cure, including motor and sensory return, after simple amputation
2		RL	Pericottis, tibia	Pain on weight bearing requiring crutches. Coldness, cyanosis, hyperhidrosis. Atrophy calf	Complete relief
		LL	Soft tissue wound, foot	Pain on weight bearing requiring crutches. Moderate edema, cyanosis, weakness and atrophy calf	Moderate improvement on weight bearing. Walks without cane but limps. Still some pain. Feet warm and dry. Edema less
3		LL	Soft tissue wound, foot	Pain on weight bearing requiring crutches. Coldness, cyanosis, slight edema. Atrophy calf	Much improvement. Pain only after walking 3 miles or more. Feet warm, dry well colored. Edema was first noticed then disappeared
		L	Simple fracture, metatarsal	Pain on weight bearing causing limp. Slight edema, cyanosis, weakness, coldness, and atrophy	Much improvement. Pain after walking 3 miles. Edema less. Feet warm and dry. Foot stronger
4		LL	Chip fracture second and third phalanges	Pain on weight bearing requiring cane. Slight edema, cyanosis, weakness	Steady improvement and then complete relief
5		RL	Soft tissue wound, foot	Pain on weight bearing. Moderate edema, cyanosis, reduced sensibility. Atrophy and weakness	Much improved. No discomfort until walking more than 1 mile. No edema. Feet warm and well colored
6		RL	Soft tissue wound, foot	Pain on weight bearing causing limp. Marked coldness, cyanosis, hyperhidrosis. Weakness and atrophy	Marked improvement. No discomfort until walking more than 1/2 mile. Feet warm, dry well colored
7		RL	Foot crushed	Pain on weight bearing requiring cane. Slight edema, coldness, cyanosis, hyperhidrosis. Weakness, atrophy, hyperhidrosis	Much improved. Able to walk 3 or 4 miles without pain. Feet warm, dry well colored. Still slight edema. Feet stronger. Sensation normal
		RL	Compound fracture	Moderate burning rest pain, increased with dependency. Moderate edema, cyanosis, coldness	Much improved. Pain much less. Edema less. Feet warm. Slight cyanosis in dependency
		RL	Simple fracture	Moderate burning pain at rest, cyanosis, coldness. Partial peroneal palsy	Much improved. Pain much less. Feet warm, dry well colored

existed cold sensitivity was diminished. The limbs were dry warm and well colored. Hypesthesia which had been present in 1 patient was considerably improved (Case 4). Two individuals subsequently required corrective operative procedures upon the affected limb which were followed by prompt healing of wounds (Cases 1 and 2).

In Table V are summarized the data concerning 2 patients for whom the operation was performed primarily because of the persistence of chronic ulcers¹ (Fig 5 a). In both repeated efforts at skin grafting had failed

but healing occurred fairly promptly after sympathectomy (Fig 5 b). In 1 individual (Case 2) it was apparent before sympathectomy was performed that transfer of full thickness skin would eventually be required, but it was felt that the chances of success would be enhanced if this could be done after epithelialization of the ulcer and correction of the vasospastic disorder.

In the case of all patients treated by sympathectomy strenuous active exercises were insisted upon after a short period of convalescence. It was the common experience that this could be accomplished better and with little or no discomfort after the operation,

¹As 3 other patients chronic ulcers healed satisfactorily with rest and saline compresses.

Fig. 5. Healing of chronic ulcer following sympathectomy. a, left. Ulcer of leg in a patient with a posttraumatic vasomotor disorder of 1 year's duration. Bed rest, compresses locally small deep grafts, and split thickness grafts had failed to bring about healing. b, Seven weeks after sympathectomy. Almost complete healing of ulcer has occurred.

and that steady subsequent improvement occurred as the individual continued to take advantage of his increased ability to perform physical exercise.

Effect of Treatment upon Osteoporosis

In 24 cases roentgenograms made at the time of admission and then some months after institution of treatment, were available for study. In 11 of the patients no alteration in the degree of osteoporosis was noted during their hospital stay. In this group the original films showed slight osteoporosis in 2, moderate in 8, and marked in 1. They had been taken from 3 to 14 months after the initial trauma, with an average of 8.8 months, while the final roentgenograms were obtained from 4 to 17 months after the injury, with an average of 10.5 months. There was thus an average elapsed time interval of observation of 1.7 months.

The 13 remaining patients in the group demonstrated definite improvement in regard to osteoporosis. The original films were taken from 2.5 to 6 months after the initial trauma, with an average of 4.9 months, while the ones first revealing a reversal toward the normal state were obtained from 5 to 12 months after injury. Thus there was an average interval

of 4.1 months between the original films and those indicating improvement. The first roentgenograms showed slight osteoporosis in 1, moderate in 6, and marked in 6. Of the 6 patients originally demonstrating marked changes, 1 showed normal bone structure in the final film, 4 had only moderate osteoporosis, while in 1 there was only a slight improvement. In 3 of the 6 individuals who initially had moderate osteoporosis, evidence of only mild involvement was now present, while in the other 3 the roentgenograms revealed a normal or almost normal condition. The 1 patient who had slight osteoporosis originally had normal appearing bones on the last examination.

In comparing the type of treatment with the changes in osteoporosis, it is of interest that 4 of 9 patients treated by exercise, physiotherapy, or psychotherapy, and 9 of the 15 sympathectomized individuals showed some improvement in this state. Two of the patients treated by sympathectomy in whom no change in the degree of osteoporosis was subsequently observed had sustained fractures of long bones requiring prolonged immobilization before operation, and it is possible that the factor of continued disuse may have played a role in the persistent osteoporosis.

TABLE IV. EFFECT OF SYMPHETECTOMY IN PATIENTS WITH EXCESSIVE SYMPATHETIC ACTIVITY

[illegible]

DIST 108

For several reasons we have purposely limited this study to an analysis of our experience with military personnel treated in a vascular center. The advantage of using only soldiers in the investigation lies in the opportunity which was afforded to follow them carefully for as long a period of hospitalization as was required. Furthermore in all of them the same motive was present with regard to the possible rewards arising from continued disability. In contrast in a comparable but smaller group of civilian patients whom we have studied much more difficulty was encountered in attempting to analyze the results. The individuals varied considerably in

age and in fact is tending to make profitable or futile the persistence of complaint. Most of them were hospitalized for only short periods of time and our observations were limited to those intervals and to office visits. In general however experiences with our civilian and military patients have complemented one another. The manifestations of the post-traumatic disorders and the results of treatment have been much the same in both groups.

The main point of interest regarding therapy which can be derived from the present study is that the degree and duration of physical disability associated with posttraumatic stress-motor disorders are dependent in great part upon the amount of time that elapses between

TABLE V—EFFECT OF SYMPATHECTOMY IN PATIENTS WITH CHRONIC ULCERS

Case	Operation, months after injury	Extremity involved	Original injury	Site of ulcer also	Other data	Results
		RL	Simple fracture tibia and fibula, evulsion of skin	Over internal malleolus 2x cm.	Split, sliding full thickness and pedicle grafts had failed. Pain on weight bearing; edema, cyanosis and reduced oxillometry. Foot cool but warmer than normal one	Ulcer healed rapidly and remained healed. Walking much improved, foot warm, dry of good color. Edema improved
		LL	Compound fracture fibula	Lateral surface leg 4x3 1/2 cm.	Small, deep and split grafts had failed. Aching rest pain; pain on weight bearing; edema, cyanosis, coldness and hyperhidrosis.	Ulcer healed rapidly. Subsequent transfer graft. Foot warm, dry well colored; hyperhidrosis gone; edema less; no pain on weight bearing

the onset of the condition and the initiation of active and effective therapy. In most of our patients early therapy was negligible and as a result, distressing sequelae persisted for many months necessitating prolonged hospitalization. In contrast was the generally satisfactory course of events in our civilian patients who were treated actively soon after injury. The period of incapacitation was much less especially when possible financial compensation was not a factor in the case.

After a period of disuse certain changes take place which are exceedingly difficult to correct. Among these are osteoporosis, muscle atrophy and a rather fixed mental attitude which hampers return to normal activity. The last factor may be due either to fear of discomfort, discouragement concerning recovery, some motivation to prolong the disability as desire for compensation or other rewards of invalidism such as avoidance of duty in the Army.

A patient with a painful or edematous extremity or one with distressing coldness and hyperhidrosis has a strong urge to keep it at rest. Disuse itself may bring about a reduction in blood flow, coldness, cyanosis, hyperhidrosis, edema, and osteoporosis—all alterations which are also part of the posttraumatic syndrome. As a consequence, it is often difficult to evaluate the relative roles of the trauma and the reflexes initiated by it, on the one hand and of the resultant disuse on the other.

It is also important to keep in mind the fact that emotional stress and instability and certain of the more clear-cut neuropsychiatric conditions are often associated with increased sympathetic activity, and that not infre-

quently those who have sustained an injury may bring such emotional and psychiatric mechanism into play. It is necessary therefore to take into consideration the factors of disuse and psychiatric manifestations in any study of patients with posttraumatic vasomotor disturbances.

Numerous individual reports testify to the value of various therapeutic measures such as voluntary motion and weight bearing (13), procaine sympathetic blocks (5, 7), penarterial sympathectomy (1, 3, 4, 6, 7) and excision or procaine infiltration of painful scars or thrombosed vessels (5, 9). Local anesthetization of the injured area seems to be not only of value in treatment but possibly also in preventing the development of posttraumatic disorders (7, 12). Unfortunately it is impossible to establish from the data recorded in the literature the incidence of failures with the various methods of treatment. Our own experience both with civilian and military patients emphasizes the importance of evaluating carefully all possible therapeutic aids in any given case and of neglecting no useful adjuvant in treatment.

SUMMARY AND CONCLUSIONS

Although patients who have sustained trauma to an extremity ordinarily only have symptoms which are due to the local tissue injury, a certain number have superimposed upon these complaints additional manifestations which can be explained only on the basis of some reflex activity initiated by the trauma. These difficulties fall into the category of posttraumatic vasomotor disturbances. The present report deals with a series of 142 soldiers suffering from such afflictions.

Generally in our patients the initial clinical picture was that of intense vasomotor activity and later this finding was almost invariably present. The primary manifestations in the acute stage were predominantly those of pain and swelling although in a lesser number they consisted of coldness, hyperhidrosis and cyanosis. Later in the disease the commonest complaints were those of pain on exercise and weight bearing and swelling. Coldness, cyanosis, and hyperhidrosis were frequently noted and in some patients, a distressing cold sensitivity. Many individuals had edema present at rest, or more often when the limb was dependent. In those in whom skin had been denuded ulceration tended to persist.

With regard to early therapy the conclusion was reached that proper care should be given to the local injury itself such as débridement, removal of foreign bodies, reduction of fracture, and the active treatment of infection. Although it is important to utilize immobilization and bed rest when the local trauma necessitates such measures, for the most part as early immobilization as is possible is advisable. In fact, some individuals can overcome the posttraumatic syndrome shortly after injury by simple perseverance in forced active exercise. It is essential to instill in the patient confidence in his ability to make a satisfactory recovery to eliminate any tendency toward chronic invalidism and to correct any existent psychiatric ailment.

In many patients, however such simple expedients do not prove to be satisfactory therapeutic measures and hence other procedures must be utilized. Among these is procaine sympathetic block, which not uncommonly eliminates pain as soon as the injection is completed causes the extremity to assume a normal color and results in the disappearance of hypesthesia and improvement in motor function. Although often a single injection may be sufficient, in some patients a series of blocks is necessary. If repeated sympathetic blocks produce a good but transient effect, sympathetic ganglionectomy may result in a permanent cure.

In the treatment of the later stages of posttraumatic vasomotor disorders, the situation is complicated both by the fixed mental atti-

tude of the patient which is that of the chronic invalid and the extensive atrophy and motor weakness which undoubtedly result not only from the initial difficulty but also from the superimposed disuse. It is important to utilize psychotherapy in encouraging continued and gradually increasing active exercise of the affected limb and to employ more specific psychotherapeutic measures in those instances in which psychiatric factors are a definite accompaniment, if not the primary basis, for disability. Regardless of any other type of treatment it is important to avoid edema by a period of bed rest and elevation of the limb if necessary and the use of elastic support. In general sympathetic blocks are of little avail as a therapeutic means when the syndrome is of long duration, but they may prove very useful in some instances, particularly where the manifestations are primarily edema or evidence of increased sympathetic activity. If the above means of treatment have been given adequate trial and yield unsatisfactory results sympathectomy should be considered. In properly selected cases it results in excellent recovery. In the treatment of the late manifestations the duration of therapy is necessarily longer and a more intense program is required than in the early phase of the posttraumatic disorders. In addition, there is considerably less likelihood of a completely successful outcome.

CARCINOMA OF THE VULVA

Report of 313 Cases

JAMES P. PALMER, M.D., MARVIN G. SADUGOR, M.D. and
MELVIN C. REINHARD, M.A., Buffalo, New York

CANCER of the vulva is considered to be a relatively rare malignant tumor. From our records of approximately 8,000 gynecological malignant tumors, the incidence of cancer of the vulva is 3.88 per cent of all cancers of the female genitalia. As shown by Pack, the incidence is only one half of one per cent of the total number of cancers, or 3.2 per cent of all cancers of the female genitalia. A review of the cases brought forth in the literature during the past 3 decades reveals an apparent great increase in this type of malignant growth, an increase which may be real or may represent merely a relative increase in the total number of patients admitted to the various institutions as a result of the wide dissemination to the lay people of information concerning cancer; it may be the result of increased knowledge about the disease among the medical profession, or it may be because the average age of the population has increased during the past 30 years.

Schreiner and Wehr reported 118 cases of carcinoma of the vulva from this hospital during the period from 1913 to 1933 inclusive. They gave in the 5 year free of disease category 72 cases from 1913 to 1928. From 1933 to 1947, 195 additional cases of carcinoma of the vulva have been seen at the Roswell Park Memorial Institute. In this paper we shall consider first, for general statistical purposes, the total number of patients, 313, admitted from 1913 to 1946, and second, in order to evaluate the results of treatment, we shall report the results in 170 patients admitted from 1929 to 1941, so as to obtain the 5 year end results.

The average age at admission for the 313 patients was 61.5 years. This figure agrees

with the average age of 60 reported by Pack for 117 patients. The peak age incidence in relation to the 1940 census of New York State, fell between 70 and 74, 65 per cent of the patients being in the age group 50 to 75, 16 patients, or 5.1 per cent, were below the age of 40, while 40 patients, or 12.8 per cent, were above the age of 75. The youngest was 6 and the oldest 96.

The most common age of menarche in the series was 14, the youngest 9 and the oldest 28. This is an average distribution and gives no indication of a relationship between menarche and cancer of the vulva. The weighted mean age of menopause was 48. However, a menopausal age distribution curve showed a peak at 52, the youngest being 32 and the oldest 64. Eighty per cent of the patients had passed the menopause, which indicates that carcinoma of the vulva is predominantly a postmenopausal or so called degenerative disease.

Considering the marital status of this group of 313 patients, it was found that 284 were married, 247 having borne children or miscarried, while only 29 were single. This is a ratio of 10 to 1 of married to single.

An interesting point concerning the various nationalities and races of the patients was observed. There were no women of negro or Jewish extraction found in the entire series of 313 cases.

The primary complaint occurring in 160 patients was itching and pruritus. The next commonest, occurring in 122 patients, was swelling or perception of the lesion by the patient herself, causing her to seek medical care. Discharge, pain and bleeding were found to be relatively infrequent primary symptoms. Leucoplacia was present in only 12 per cent of the cases, which is considerably less than that reported in other series of rela-

tive size (Smith and Pollack and Taussig 5 6) Only 4 patients were diabetic and 3 had positive Wassermann reactions which seems to indicate that syphilis and diabetes have very little or no bearing on the etiology of cancer of the vulva.

The duration of symptoms before admission to the institute varied widely from 1 month to several years, but it has been observed that the duration of symptoms during the past decade is markedly less than in the previous decades also that the lesions are not as far advanced as they were 10 20 and 30 years ago

The histological forms or types present in this series were as follows: epidermoid carcinoma, 300 malignant melanoma 7 adenocarcinoma, Bartholin's gland 1 myosarcoma, 1 and basal cell carcinoma 4.

The classification given shows that over 95 per cent of vulvar cancer cases observed in this series were epidermoid in origin. This percentage is somewhat higher than that re-

ported in the literature. Smith and Pollack reported 84 per cent of epidermoid carcinoma in their series of 228 cases. Taussig (6) in his series reported 90 per cent. The percentage of malignant melanomas found in this series was 2.2 per cent which closely approximates the average percentage found in other series of the same type. Adenocarcinoma, Bartholin's gland origin and sarcoma of the vulva are very rare. This series showed 1 case of each. Only 16 patients of the 313 (5.1 per cent) had other primary malignant tumors.

The youngest and the most interesting case in this series was a 6 year old child with a myosarcoma of the vulva. This patient had been to her family doctor in March 1944, 1 month after the appearance of the lesion. The child was hospitalized and the tumor mass was removed. It was reported to be myosarcoma. There was an immediate recurrence, eventually involving the entire labia majora. The patient was admitted to the Roswell Park Memorial Institute July 1944 5 months after the original appearance of the lesion. Clinically this growth involved the fourchette and left labia. The mass was excised and roentgen therapy was given. A pathological section from the vulva showed a malignant tumor made up of large and small spindle cells. When last seen 4 years later there was no evidence of disease and the general condition of the patient was good.

It has been customary at this Institute to use a simplified classification consisting of three groups as follows:

Group I—Included those patients who were admitted here without any form of previous treatment, and in whom the disease was confined to the vulva, regardless of its size.

Group II—Included those patients admitted without previous treatment in whom at the time of admission the lymph nodes in one or both groins were distinctly enlarged and firm and were believed to be metastatic.

Group III—Included all patients with vulvar disease who had received treatment, surgery, radiation or a combination prior to admission here.

The 72 patients treated from 1913 to 1928 inclusive, on whom Schreiner and Wehr reported 5 year end results, were divided into

the same clinical groups. The results are as follows

	Total	N.E.D. 5 years	Percent- age
Group I	19	6	31.5
Group II	24	0	0.0
Group III	20	2	7.0
	73	8	11.1

N.E.D. no evidence of disease.

The present paper reports the 5 year end results in 170 patients treated from 1929 to 1941 inclusive, with larger doses of more heavily filtered radiation plus more extensive surgery. In all of these patients vulvar cancer was proved by histological section. Prior to 1929 very few patients had more than local excision or local coagulation of the lesion. Subsequent to 1929 an increasing percentage of the patients had total simple vulvectomy with the metastatic nodes being treated with irradiation. Since 1941 more radical surgery is being used, consisting of total vulvectomy and superficial groin dissection, unilateral or bilateral when there are definite inguinal nodes which are thought to be metastatic when there are no definite nodes or when there are soft tender nodes which are thought to be inflammatory, groin dissections are omitted. These patients are followed closely and if the soft tender nodes regress, no groin surgery is performed. We have not used the so called Taussig or Basset type of radical groin dissection in any case of carcinoma of the vulva and note that Smith and Pollack conclude that best results in their cases were obtained when a vulvectomy with bilateral superficial groin dissection without removal of the iliac or deep inguinal nodes was performed.

In the inoperable cases, whether inoperable because of the disease or because of the patient's poor general condition and in post operative recurrent cases whether the recurrence be local or in the nodes x ray therapy is used and often gives marked prolonged relief and occasionally apparent cure.

The 5 year end results are shown in Table III. It can be observed from this table that there is a marked increase in the cure rate in all 3 clinical groups as compared with the previous report of Schreiner and Wehr. This may be attributed to the more radical surgical

TABLE II.—COMPARISON OF METHODS OF TREATMENT

Group I			
	Coagulation or surgery	Radiation	Combined surgery and radiation
No evidence of disease	5		
Alive with disease			1
Died of disease		3	
Lost			1
Died of other causes		1	4
Total	6	4	15
% Cure rate	83.4		55.3
Group II			
No evidence of disease	0		0
Alive with disease			1
Died of disease		5	3
Lost			
Died of other causes	0

Lost			
Died of other causes			
Total		1	17
% Cure rate			23.3

procedures and to the increased radiation dosage used subsequent to 1928. However to make a comparative study of the relative merits of surgery and radiation, the data appearing in Table II were rearranged according to the 3 methods of therapy, surgery alone, radiation alone, and a combination of both. It will be noted from Table II that of the 48 patients of group I 6 received surgery alone, 4 received radiation alone and 38 received a combination of both. While the numbers 6 and 4 are too small to yield results to which any significance can be attached, the results are highly suggestive that surgery is far superior when one considers that 5 of the 6 patients treated with surgery alone survived while on the other hand none of the 4 patients

TABLE III—FIVE YEAR END RESULTS

	Number admitted	Number treated	Number free of disease	Alive with disease	Died of disease	Lost	Died of other causes	Cure rate absolute %	Cure rate relative
Group I	48	48	46		1		3	94	94
Group II		70		1	59			1	
Group III	30	48	10	3	3			20	20.3
Total	78	166	66	4	63	4	7	36	37

treated with radiation survived. This is further substantiated when considering the 27 patients in group II who received radiation only and yielded no survivors.

Evaluating the combined therapy of the 38 patients in group I 32 received radiation to the groin only the primary site receiving none at all. This would seem to indicate that the radiation was administered for prophylaxis only and its role in the ultimate result of the treatment is difficult to analyze. On the other hand when considering the corresponding group II cases, that is the group which received treatment in the form of surgery and radiation we find that here the radiation to the glands had a definite effect in improving end results because all of these patients had nodes and in no case did the surgical procedure touch the gland-bearing region. Therefore it would seem logical to conclude that the radiation must have been beneficial in controlling the disease.

The question has been raised by Smith and Pollack as to the role of the pathological grading of the disease in relation to end results. Their figures tended to prove a higher cure rate for the pathological grade I or well differentiated tumors as compared with grades II and III or the less well differentiated tumors. Of the 170 cases considered in Tables II and III which had proved positive sections, there were 147 which the pathological department could grade using a modified Broder's classification.¹ The grading and end results of the 147 cases which could be graded are shown in Table IV. All patients who were alive with disease or who had been lost or died of other causes within the 5 year period are included with those who died of the disease thus giving an absolute cure rate for the different pathological grades.

¹Broder's Grades II and III combined.

It seems from Table IV that the survival rate is independent of the pathological grade of the disease. However further to substantiate this opinion the pathological grades were subdivided into the clinical groups. These results were similar to those in Table I in that no relationship is shown between pathological gradings and cure rate. We feel that these results tend to disprove Smith and Pollack's conclusions regarding the importance of pathological grading.

Several authors have attempted to show the relationship between end results and the site of the original lesion such as labia majora labia minora, vestibule and clitoris. In our group of cases with a few exceptions, however the local disease was so extensive that we were unable to determine accurately the site of origin and therefore were unable to classify the disease according to this method.

CLASSIFICATION

Numerous methods of classifying the clinical extent of carcinoma of the vulva have been used and these classifications are so different as to render impossible a comparison of end results from the different types of treatment. This may well be illustrated by the following classifications taken from the literature with a discussion as to the types of treatment and end results.

1. Bervin classifies carcinoma of the vulva by groups I II III and IV which have to do with the primary lesion only and stages I II and III which have reference to the regional lymphatics. His final classification includes

TABLE IV—GRADING AND END RESULTS

	Grade I	Grade II	Grade III
Total	80	46	
Alive no evidence of disease 5 years	3	3	5
Percentage survival	3.8	2.2	3.8

groups plus stages thereby giving 12 distinct clinical classifications as follows

Group I Tumors limited to one part of the vulva (1 cm diameter) without surface ulceration or deep fixation

Group II Tumors limited to one part of the vulva with ulceration and secondary infection with or without inflammatory inguinal nodes

Group III Local tumor extending beyond the part of the vulva primarily involved and possibly beyond the vulva itself

Group IV Tumors extending beyond the vulva proper to involve the vagina, the perineum or the skin of the surrounding parts by continuity or both the perineum and the skin of surrounding parts

Stage I Small well circumscribed movable nodes quite soft and obviously inflammatory

Stage II Enlarged indurated nodes thought to be metastatic

Stage III Enlarged primary fixed nodes undoubtedly metastatic

Bervin treats these patients according to the stage, or the condition of the nodes. A primary lesion is always treated by electrocoagulation. All stages receive teloradium therapy to the groins. Patient with a stage I tumor is operated upon only if subsequent nodes appear. Stage II patients are subsequently operated upon (en bloc, superficial dissection only) if nodes do not completely regress following irradiation. Stage III patients receive no surgery to the metastatic nodes.

2. Smith and Pollack, Memorial Hospital classify the tumors as follows

Class I Tumors which show no extension (a) beyond the primary site on clinical examination, and (b) in which the regional nodes are dissected and no metastases are found on microscopic examination

Class II Tumors with inguinal nodes involved but operable as determined (a) by clinical examination and (b) by dissection of the nodes and positive biopsy findings

Class III Inoperable tumors with inguinal nodes fixed swollen leg

Smith and Pollack's patients were treated with a variety of methods of surgery and of radiation, or a combination of the two

3. Taussig classified the tumors as follows

Class I Primary tumor less than 3 centimeters in size without nodes

Class II Primary tumor 3 to 7 centimeters in size without nodes

TABLE V — COMPARATIVE END RESULTS

	Tausig	Bervin	Memorial Hosp.	R.P.M.I.
Total number cases	108	244	146	170
Number free of disease—5 years	32	65	25	45
Survival—years free of disease—5	80	26.6	25.5	25.5

Class III Primary tumor more than 7 centimeters in size with or without movable nodes

Class IV Primary tumor extending to vagina, suprapubic area with or without fixed nodes

Class V Primary tumor far advanced, with ulcerative nodes and cachexia

In Taussig's 108 cases complete vulvectomy with radical node dissection (Bastet) was done in 41 patients, vulvectomy with superficial or incomplete gland removal was done in 21 additional cases and vulvectomy only or radiation or symptomatic treatment for palliation was used in the remaining cases.

Table V is a composite end result table of large groups of cases from various clinics classified according to the outlines given and treated by the methods described, showing that regardless of classifications and methods of treatment used, the absolute cure rates are almost identical.

The classification used at R.P.M.I. Memorial Hospital has been repeated for the sake of explanation Group III

Group I includes all primary cases in which the disease is still confined to the vulva regardless of the size

Group II includes all cases in which there is clinical evidence of metastasis to the inguinal nodes, superficial or deep

Group III includes all cases in which the disease has spread beyond the vulva and inguinal nodes (secondary) which are still confined to the vulva and inguinal nodes have developed so classified because it is not possible in some cases should be clinically to the findings at the time of examination and since, in some cases, it is unable to ascertain the extent of the disease at the time of the examination elsewhere before treatment was given, it is unable to classify them as

It will be noted from the four methods of classification outlined that in two of the clinics great emphasis is placed on the extent of the primary neoplasm while in the other two clinics no consideration is given to the extent or size of the primary lesions. Also in none of the four clinics is the site of origin of the disease considered in arriving at a clinical classification although some of the clinics show very definitely that the site of primary involvement does influence the prognosis.

We do not think the classification we are using is adequate however we do not think that any of the other classifications as outlined is satisfactory. We therefore recommend that a classification employing all factors which have a bearing on the prognosis be devised and be accepted by all clinics in order that a more satisfactory evaluation of the various types of treatment may be obtained.

CONCLUSIONS

1. Three hundred and thirteen cases of carcinoma of the vulva are evaluated for statistical purposes.

2. Treatment and end results of these cases are given.

3. This series of cases is compared with three other groups of cases of an approximate number as to the absolute cure rate.

4. We conclude that thus far no marked advantage has been proved for the more radical type of surgery (Basset) if the absolute cure rate is considered.

5. We are of the opinion that there is no adequate clinical classification that uses all factors influencing end results and no clinical classification that is generally accepted. Therefore we propose that a committee should be appointed from some National Gynecological or Cancer Society to formulate an adequate classification.

URETEROSIGMOID ANASTOMOSIS

JUSTIN J. CORDONNIER, M.D., St. Louis, Missouri

THE voluminous literature on uretero-intestinal anastomosis and the multiplicity of methods for its accomplishment testify to the fact that to date no wholly satisfactory method has been found. In 1936 Hinman and Weyrauch's excellent presentation summarized all methods and fundamental principles to that time. This work was further supplemented by Hinman in 1939. Analysis of the literature subsequent to that time fails to reveal any further fundamental changes in the procedure. The method herein given has proved so successful in a small series that it is deemed worthy of presentation. It differs fundamentally from the usual methods in the following three principal points: (1) bringing the bowel to the ureter rather than the ureter to the bowel; (2) transplanting mucosa to mucosa; (3) eliminating the submucous tunnel.

BRINGING THE BOWEL TO THE URETER RATHER THAN THE URETER TO THE BOWEL

The maintenance of proper ureteral peristalsis is vitally important in any uretero-intestinal anastomosis, and it is my belief that this factor coupled with an absence of obstruction at the site of anastomosis is of paramount importance in prevention of the upper urinary tract infection which occurs so frequently following this operation. There is considerable divergence of opinion as to whether stripping the ureter causes any interference with its normal peristaltic activity. However, it would seem that avoidance of destruction of extrinsic nerve and blood supply would be of undoubted value in the maintenance of proper physiological function of the ureter postoperatively. This fact was pointed out by Wharton in 1942. As will be demonstrated later in this discussion, at the completion of the operation the ureter is practically in its original bed and no

more than 1 to 1½ centimeters of denuded ureter lie above the site of anastomosis. The rest of the ureter remains within its normal bed. Most other methods free considerably more ureter than this, and it is my belief that this fundamental difference is an important one.

TRANSPLANTING MUCOSA TO MUCOSA

Fundamentally this method was described by Chaput in 1896 who performed it experimentally on a dog and promptly abandoned it as being impractical. It is a fundamental principle in intestinal surgery that to avoid postoperative scarring and stenosis a mucosa-to-mucosa anastomosis is of vital importance. Hinman and Weyrauch offer the objection to this method that accurate approximation of mucosa to mucosa is difficult and cannot be done without gross contamination. In addition they believe that postoperative edema results in a more or less temporary interruption of the urinary stream. They also point out that the danger of peritonitis from postoperative leakage is very great. In our experience none of these difficulties have been encountered. We believe that an accurate approximation of mucosa to mucosa can be obtained with ease. There has been no interruption of urinary flow. In fact only 1 patient has failed to excrete at least 1,000 cubic centimeters of urine in the first 24 hours after operation and the output in some has been as high as 1,500 to 2,000 cubic centimeters. In addition the entire operative site is extra-peritonealized so that the danger of peritonitis is eliminated. It is felt that perhaps the objections offered by them were presented prior to the advent of proper bowel preparation with sulfathalidine or sulfasuxidine, and that with the present methods of preparation these dangers no longer exist.

ELIMINATING SUBMUCOUS TUNNEL

Production of the so-called submucous tunnel, even when carefully prepared, is apt to

From the Department of Surgery, Washington University School of Medicine and Barnes Hospital.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Los Angeles, October 18-19, 1948.

Fig

anastomosis. Minimal disturbance of the ureter can be accomplished by bringing the bowel over to the ureter for this suture (Fig 1-3). A stab incision is made through the submucosa and mucosa of the bowel. The opening should be just slightly larger than the circumference of the ureter. Care should be taken that this opening be neither too large as it is apt to leak or too small as stenosis might result. Sutures are then placed as shown in Figure 1-3. The first stitch is taken on the same side of the ureter as the previously shown anchoring stitch and is made by going through the wall of the ureter into the lumen through the

lumen of the bowel and out prior to being tied.

This procedure is then carried out around the entire circumference of the ureter producing a water tight junction. Care must be taken that these stitches be placed accurately to avoid any puckering of the anastomosis. In a normal ureter four sutures are usually sufficient to accomplish this purpose. However when a hydroureter is present any number of sutures may be used to obtain a water tight junction. No 0000 chromic catgut on an atraumatic needle is used (Fig 1-4). A second row of sutures is then placed between the serosa of the

Fig 9

ureter was transplanted anyhow with the hope that there would be some return of function.

Fig 9. Case 8. Bilateral grade II hydronephrosis. Poor case risk in series. It is hoped there will be some improvement. Patient had one attack of pyelonephritis, easily controlled. Intravenous pyelogram 10 days after operation.

postoperative leakage. Care must be taken in placing these sutures that too much ureter is not forced into the lumen of the bowel, thereby producing constriction. Figure 1 5 demonstrates closure of the posterior peritoneum with the bowel being brought over as shown in the illustration. The placing of these sutures is particularly important because it produces fixation of the site of anastomosis. They must be placed so that there is no angulation of the ureter and that it lies practically in its normal preoperative position. The sigmoid should be pulled downward slightly without producing too much traction on the anastomosis so that the ureter is maintained in a straight position. The completed closure is shown in Figure 1 6 which also demonstrates that the entire site of anastomosis is extra peritoneal at the conclusion of the operation. Figure 1 6 also shows the method used on the left side. The ureter is not brought through the mesentery but is brought out directly below the transverse portion of the sigmoid as shown in the illustration. Anastomosis on this side really easier than on the right side. It is necessary that a taenia be used as the site of anastomosis. As a matter of fact I believe the best results have been obtained

when the anastomosis was placed outside the taenia.

The same procedure is carried out on the left side as described on the right. Then the sigmoid is rolled downward to produce a straightening of the ureter and close the posterior parietal peritoneum. The end result is shown in Figure 1 7.

POSTOPERATIVE RESULTS

Up to the present time this procedure has been done in 26 consecutive cases with no mortality. Immediate postoperative complications have been almost completely absent. Three of the patients have had one attack of pyelonephritis after departure from the hospital. These have been very mild in character and all were easily controlled by sulfonamides. We have made no effort to avoid operating on patients who were poor risks. One of the patients had a rather marked hypertension with a very malignant early carcinoma of the bladder. Another had severe diabetes. Two others had had extensive deep radiation therapy with marked scarring of both ureter and bowel. These cases were certainly far from ideal but I believe presented a true test of the procedure. If it was successful in this type of patient

postoperative leakage. Care must be taken in placing these sutures that too much ureter is not forced into the lumen of the bowel thereby producing constriction. Figure 15 demonstrates closure of the posterior peritoneum with the bowel being brought over as shown in the illustration. The placing of these sutures is particularly important because it produces fixation of the site of anastomosis. They must be placed so that there is no angulation of the ureter and that it lies practically in its normal preoperative position. The sigmoid should be pulled downward slightly without producing too much traction on the anastomosis so that the ureter is maintained in a straight position. The completed closure is shown in Figure 16 which also demonstrates that the entire site of anastomosis is extra peritoneal at the conclusion of the operation. Figure 16 also shows the method used on the left side. The ureter is not brought through the mesentery but is brought out directly below the transverse portion of the sigmoid as shown in the illustration. Anastomosis on this side is really easier than on the right side. It is not necessary that a taenia be used as the site of anastomosis. As a matter of fact I believe that the best results have been obtained

when the anastomosis was placed outside the taenia.

The same procedure is carried out on the left side as described on the right. Then the sigmoid is rolled downward to produce a straightening of the ureter and close the posterior parietal peritoneum. The end result is shown in Figure 17.

POSTOPERATIVE RESULTS

Up to the present time, this procedure has been done in 26 consecutive cases with no mortality. Immediate postoperative complications have been almost completely absent. Three of the patients have had one attack of pyelonephritis after departure from the hospital. These have been very mild in character and all were easily controlled by sulfonamides. We have made no effort to avoid operating on patients who were poor risks. One of the patients had a rather marked hypertension with a very malignant early carcinoma of the bladder. Another had severe diabetes. Two others had had extensive deep radiation therapy with marked scarring of both ureter and bowel. These cases were certainly far from ideal but I believe presented a true test of the procedure. If it was successful in this type of patient

It should prove so under almost any circumstances. Both of these patients were operated upon for palliative reasons. It is too early to evaluate the end results of either the cancer surgery or the transplants. However we believe that the end results will prove satisfactory. Pyelograms of the first 8 patients are shown.

SUMMARY

1. A method for ureterointestinal anastomosis is presented.

2. Three fundamental principles are emphasized (a) minimal disturbance of the ureter from its bed the bowel being brought to the ureter rather than the ureter to the bowel (b) mucosa to-mucosa transplantation is accomplished (c) the submucosal tunnel is eliminated.

PARTIAL GASTRECTOMY IN THE WAR YEARS

DR. C. A. SCHOEMAKER, The Hague, Holland

THE surgical treatment of gastric and duodenal ulcers became a new problem in the war years (1940-1945). During the first year of the German occupation of Holland rations dropped fairly rapidly to about 1600 calories daily. The composition of the food varied considerably; it became poor in proteins and fat, rich in carbohydrates, and showed a great increase in cellulose content.

The quantity of rationed food remained practically constant during the first few years. The year 1944 brought an appreciable decrease. Serious famine swept western Holland in the winter of 1944-1945; rations dropped to 700 calories a day in November 1944, to 430 calories a day in February 1945 and finally to 200 calories a day in April, 1945.

In the beginning stomach patients were allowed extra rations, but even then the quantity of food was insufficient, especially in the large cities. Most people could not afford to buy appreciable quantities of food on the black market, so they were compelled to augment their rations with sugar beets and often even with ground tulip bulbs. The composition of the bread moreover was so bad (it consisted mainly of bean meal, pea flour or bulb flour) that it was quite unsuitable for patients with gastric ulcers.

As a result of these difficulties patients insisted on surgical treatment. They more or less had the feeling that without operation their chances of survival were small since the gastric ulcer made it impossible for them to eat a number of foods as such food would aggravate the ulcer. The surgeon on the other hand was of the opinion that the chances of obtaining a favorable result after gastric operation were poor: first because it was not possible to provide a reasonably suitable diet for an extended period of time after operation and second because the hospitals were greatly overcrowded and it was impossible to keep patients for more than a few weeks after operation. Operation involved an added risk for

the reason that the coal shortage was becoming so acute that heating of the operating theater had become practically impossible.

Despite all this a large number of operations were performed. The figure was higher than usual because in Holland too the number of gastric and duodenal ulcers was considerably on the increase. This increase started in 1934 and during the war the number of ulcer patients admitted to the hospitals became even greater. Relatively more large callous ulcers were noted. True, we did not see the *ulcère géant* as big as the palm of the hand as described by Moutier and Gutman or such as was encountered by De Langen (1947) and Jordan (1946), but we did observe a remarkably large number of big ulcers among them being one of $1\frac{1}{2}$ inches and one of 2 inches in diameter. To our amazement and reassurance the direct results of operation were so much better than anticipated that we were encouraged to recall our patients for check up after a few years in order to judge their progress.

We have consistently reserved our decision to operate until at least one attempt to cure the ulcer by conservative measures has been made and has not been successful. We did not depart from this rule during the war. During this period we considered an obvious case of retention more an indication to operate than previously. Consequently we operated immediately in the presence of serious gastric hemorrhage when the gastric or duodenal ulcer had been located by means of the x-ray and the hemorrhage had recurred.

The considerable amount of blood necessary for transfusion in such operations constituted a great though not insurmountable difficulty. It was surprising even in the worst period of starvation that we could secure sufficient donors.

Our war time experience may contribute much toward improving our views regarding the origin of gastric and duodenal ulcers.

For example Professor Deelman of Amsterdam has repeatedly published reports of his

Fig. Schoemaker modification of Billroth I. A, Diagrammatic survey. The lesser curvature is for the greater part removed. The branch of the vagus nerve which runs downward alongside the lesser curvature is severed fairly high up. B, On the freeing of the greater curvature the duodenum is severed. C, The large clamp is placed fairly high up on the stomach. The stomach is severed along this clamp and along stomach-clamp. The large half of the clamp is removed and D the edge thus freed is sutured. After making second suture the new lesser curvature is made. Of the end-to-end connection between the remaining stomach opening and the duodenum the rear wall is sutured first. E, The serosa suture to the rear. F Mucosa suture. This is followed by a serosa suture to the front (not shown.)

investigations on the subject of the formation of duodenal ulcers. He confined himself to ulcers of the duodenum because it appeared to him that the process here is subject to more rapid changes in either direction both as to aggravation of the condition and as to the healing of the ulcer. It became clear that the mucous folds never alter their position and that the deepest folds generally lie at the front

and back. Under the influence of spasms, atrophy of Brunner's glands takes place, chiefly at the base of the deepest folds with epithelial spreads into the muscularis in the form known to us as the U.D. Thus a primary role is attributed to spasms.

Van Eck (1947) arrived at the same conclusion from an entirely different angle. He determined the secretion of gastric juices not

at night, as Sandweiss (1946) did, but throughout the day by a standard diet spread over 3 meals, plus 1 glass of milk. This regimen produced peculiar results with certain constant characteristics for the various stomach disorders. It appeared that, despite the fact that in ulcer patients whose stomachs had previously shown by x ray examination that a barium meal passed normally, a large quantity of gastric juice nevertheless remained behind after a meal. This fact too points unmistakably to a derangement of the normal reflex mechanism of gastric evacuation caused by spasms (see Fredenhagen 1947).

The important part played by spasm in the formation of ulcers has now also been confirmed by war time experience as has been pointed out by Professor Boerema (1947) of Amsterdam.

The occurrence of intensified peristalsis and intestinal spasm became so frequent during the occupation that in the last years almost every body suffered for longer or shorter periods from diarrhea and increased flatulence. Not only the altered composition of the food but also psychic strain must have caused this. Affections which are allied to spasms, such as ileus of the small intestine and fissure prolapse of the anus and rectum were much more frequently encountered during the war than in peacetime (Boerema, 1947).

The great increase in the number of ulcer sufferers during the war must undoubtedly be closely connected with the strong inclination to spasm. These spasms were so often observed during x ray examination that many ulcers were mistaken for carcinoma. Of the 129 ulcers operated upon by us during the last year of the war, 6 showed the characteristics of carcinoma but upon microscopic examination of the prepared specimens were found to be benign ulcers.

That an increased hydrochloric acid content of the gastric juices should exert a primary influence is not very likely, because during the hunger period an achylia gastrica was very often met with (see Palmer and Nutter 1940). The opinion at present again being voiced that psychic strain is a factor giving rise to gastric and duodenal ulcers is confirmed by our experience: it was not so much fear of the

often inhuman measures taken by the Germans as the daily recurring vexation at their behavior. This can be judged only if one has experienced it himself.

TREATMENT

In treating most of the patients we used the Schoemaker modification of the Billroth I resection. The elder Schoemaker described this method in *SURGERY GYNECOLOGY AND OBSTETRICS* in 1921.

After the greater and lesser curvatures have been loosened and the duodenum is freed to a point beyond the ulcer, the duodenum is severed between clamps. A large double clamp is placed high up on the stomach and obliquely to this a stomach clamp. After removal of the part of the stomach to be resected, half of the large clamp is taken off to allow the mucous suture to be made and on removal of the other half the new lesser curvature is prepared with a Lembert suture. The two remaining stomach clamps are brought together and an end-to-end suture is made in two layers (Fig. 1). If the left gastric artery is ligatured high up in the lesser omentum the stomach may always be drawn down sufficiently to perform a large resection.

By placing the stomach clamp high up in this manner all the branches of the vagus nerve that communicate the stimulus for increased peristalsis or spasms are in all probability severed. As described years ago (see among others Mueller 1924) stimulation of the vagus with a small dose of pilocarpine produces increased peristalsis; with a large dose spasms are induced. It is known that the vagus branches which run downward along the small curvature are the ones that control the movements of the stomach (see Fig. 1a).

As a rule a Billroth I was performed. Only when as a result of infiltration the duodenum could not be loosened beyond the ulcer was resection for exclusion according to Finsterer (1918, 1933) that is, a modification of Billroth II performed. We are of the opinion that when an adequate portion of the duodenum can be freed beyond the ulcer to close it for a Billroth II, one might just as well establish a connection according to the Billroth I operation. Only when a large area of inflammatory

infiltration was noted around the duodenum and when the patient was in bad general condition was a posterior retrocolic gastroenterostomy done as an exception. If the stoma is properly made satisfactory results should follow (Gray and Sharpe 1946).

When hemorrhage was profuse and recurrent resection was always carried out without a search being made for the bleeding blood vessel. In such cases liberal transfusions of blood were given.

The total number of patients operated upon during the last 3 war years was 129. Of these 40 had ulcer of the stomach and 89 had ulcer of the duodenum a proportion of 1 to 2.2.

Of the patients with gastric ulcers 36 were men and 4 were women (9 to 1) and of the patients with duodenal ulcers, 81 were men and 8 were women (10 to 1) (see Gainsborough and Slater 1946). The total mortality was 4 (3.1%). Of these 4 cases we note the following.

A Billroth I was done in a 44 year old patient with a gastric ulcer. patient died of pulmonary embolism.

Two patients with extensive inflammatory tumors of the duodenum were subjected to resections for exclusion according to the method of Finsterer. Both patients were in such poor general condition that they could no longer overcome the peritonitis which developed as a result of the inadequate duodenal stump.

The fourth patient underwent a serious operation to relieve an extensive hemorrhage associated with an ulcer which had penetrated deeply at the back of the duodenum. During the Billroth I resection the ductus choledochus had to be ligated before the ulcer was removed. A cholecystoduodenostomy was made. Despite the use of liberal blood transfusions the patient died of postoperative shock.

Of the 129 patients operated upon 111 had Billroth I resections, 4 patients had gastroenterostomies and a cutout resection was performed in 14 patients.

RESULTS

Follow up examinations were possible early in 1948 in 105 patients. It appeared that not

a single patient had died of starvation. All but 10 patients had been able to tolerate the poorly digestible food during the famine. Of the 94 patients who had had a Billroth I resection 86 showed what might justly be termed 'very good' results for they were no longer on diet the stomach could stand peas, beans, cabbage and the like. A normal meal could be taken by all. However some complained that exceedingly large quantities gave them a heavy feeling in the stomach. They were all carrying on their normal pursuits. Their general dietetic condition was normal and there was no anemia. In 6 patients (6.4%) the result could be considered to be satisfactory but there were a few complaints. In 2 of them large quantities of food at a time could not be taken so that they had to have a fourth meal in addition to the 3 main meals. One patient suffered from a scar hernia. Two patients still had stomach complaints. Two patients did not really complain about their stomachs but were psychically so deranged that they could not pursue their normal activities.

Röntgenograms failed to show any sign of a recurrent ulcer in any of these 6 patients. Complaints from 2 patients (2.1%) were such that a second operation became necessary.

One of them was operated upon again in another hospital where a secondary stomach resection was performed according to the Reichel Polya technique for treatment of ulcer deep down in the duodenum. (In addition, a mock operation was performed on this patient who played an important part in the underground movement in order that he might be kept out of the hands of the occupying power.)

It will be noted from our study that heavy psychic burdens are an important factor in cases of recurrence.

The second patient with serious complaints was, in the opinion of the x ray specialist, suffering from a new ulcer which had formed near the new stomach outlet. The operation carried out elsewhere revealed no ulcer. The stomach passage seemed to be obstructed, as a result of growing out of shape of the ligamentum teres hepatis as a broad strip over the anastomosis. Most of this ligament was

removed and the patient made no further complaint.

Of the 4 patients who had gastroenterostomies made because of their poor general condition 2 could be traced. Neither of them had had any complaint after the operation. One of them committed suicide 4 years after operation a fact which again serves to confirm our opinion that many ulcer patients are psychically unbalanced.

It was possible to re-examine 7 of the 14 patients who had had cutout resections. Six of them had no complaints. One of them complained a year after operation of pain when his stomach was empty. On re-examination (3½ years after operation) an ulcer was indicated on the anastomosis for which the patient is now undergoing dietetic treatment.

To sum up of the total number of patients re-examined (105) only 2 recurrences were established (1.9%). Our results are no less favorable than those obtained by Schoemaker Sr in the years 1923 to 1937 (Ten Kate 1940) and seem very satisfactory if we compare them with those of others. Still 1936 Lake 1937 Lahey and Marshall 1937 Graham, 1938 Steinberg 1940, and Walters and Claggett 1940.

THE DUMPING SYNDROME

Finally we would record a few remarks on the so-called dumping syndrome (See Berkman and Heck, 1945; Zollinger and Hoerr 1947). The syndrome did not occur among our patients. This is to be expected if one bears in mind that with a Billroth I operation the evacuation of the stomach is only slightly more rapid than in a normal stomach.

The complaints which were occasionally made on the tenth day after the operation on consumption of the first quantity of solid food were caused by the difficult passage of the food past the anastomosis. When the diet was slightly reduced the complaints vanished in all patients after a few days.

The occurrence of diarrhea as described in the dumping syndrome was such a general phenomenon in war time that no value could be attached to it. The only deviation among our patients which points in this direction was the following when they were asked emphati-

cally about it some patients stated that they were troubled by it when they rounded off a hearty meal with a dessert which was rich in carbohydrates, such as custard or sweet gruel. This was the case in 4 of the patients re-examined.

A few patients had occasional attacks of giddiness and have had to lie down. In my opinion this phenomenon indicates a rapid carbohydrate absorption and so is not the real dumping syndrome. For that matter not a single patient made these complaints when the excessive quantity of carbohydrates was omitted at the end of the meal.

The absence of the 'dumping syndrome' with the Schoemaker modification of the Billroth I operation was confirmed a short time ago in material published by the Mayo Clinic. According to Custer Butt and Waugh (1946) the dumping syndrome occurs in its serious form in 28 of 500 resections based on the Reichel Polya technique. This fact impelled the surgeon Waugh to use a different method of stomach resection. No permanent 'dumping syndrome' occurred among the 37 patients operated upon by him according to the Schoemaker modification of the Billroth I operation (see also Ogilvie 1947).

Our experience gives us confidence in our opinion that the latter operation gives the best results.

SUMMARY

A description is given of the difficulties which arose in the surgical treatment of gastric and duodenal ulcers in Holland during the war. Despite these difficult conditions the results on re-examination of the patients did not appear to be less favorable than those reported under normal circumstances: the total mortality was 3.1 per cent.

Of 102 patients re-examined 94 (90%) had no complaints. 8 had complaints which were due not to a recurrence. 2 patients had a recurrence of the ulcer and 1 patient had a stomach complaint caused by adhesions.

The favorable results among which were the absence of the dumping syndrome are a reason for us to apply the Schoemaker modification of the Billroth I technique for stomach resection whenever possible.

A DOUBLE JEJUNAL LUMEN GASTROJEJUNAL ANASTOMOSIS

Pantaloons Anastomosis

M. E. STEINBERG M. D., Portland, Oregon

IN 1933 and again in 1934 I published studies on the role of spasm in the etiology of peptic ulcer. In one of these studies a larger jejunal lumen was created by anastomosis of two parallel jejunal segments in an antiperistaltic direction. This enlarged jejunal lumen was anastomosed to the proximal part of the stomach. The distal gastric segment was closed according to the method of Devine and Von Eiselsberg and at the same time alkaline duodenal contents were diverted from the gastrojejunal anastomosis by the Y anastomosis of Roux. The enlarged jejunal lumen created by this procedure counteracted any obstruction produced by spasm of the jejunum at the site of anastomosis. None of 4 dogs developed jejunal ulcers during a period of 72 to 225 days after creation of the double lumen jejunal anastomosis. However 9 out of 12 dogs developed jejunal ulcers when the usual single lumen jejunal loop was used in a similar manner. One of the latter animals was found to have a jejunal ulcer 3 centimeters in diameter with a deep crater. The single jejunal loop was reconstructed with formation of a double lumen anastomosis without disturbing the area of ulceration. One month after this reconstruction operation the deep crater of the ulcer was found to be partially healed. Not only did the 4 dogs with the double jejunal lumen anastomosis fail to develop ulcers they also gained weight and remained in good health.

In 1943, while performing a gastrectomy for duodenal ulcer I observed that the jejunum was unusually narrow with spastic walls. The narrow lumen of the jejunum and the spasticity of its musculature did not change during the gastrectomy. I was apprehensive that the anastomosis of the gastric remnant to a je-

junum with such an unusually narrow lumen would result in emptying difficulties and might predispose to the formation of a jejunal ulcer. Recalling my experiments reported in 1934 with the double barrel anastomosis which failed to result in jejunal ulcerations and which gave no emptying difficulties I established gastrojejunal continuity by the method mentioned. The patient made an uneventful recovery and has remained in good health since.

Varco, Code, Walpole and Wangenstein invariably produced peptic ulcers in normal dogs by daily injection of histamine in beeswax. Lannin made extensive experiments with the histamine in beeswax preparation to determine which of the various gastrojejunal anastomoses gave the most protection against jejunal ulcer. He was able to produce jejunal ulcerations in all dogs subjected to gastroenterostomy and to the Devine exclusion operation. In our experiments we have performed gastroenterostomy and the Devine exclusion operation but in place of the standard single lumen jejunal anastomosis we have employed the double lumen jejunal anastomosis. Two normal dogs were given daily injections of histamine in beeswax. Both of these animals developed duodenal ulceration. Of 3 dogs with the double barrel jejunal anastomosis only 1 developed jejunal ulcerations. The 2 other dogs remained in perfect condition. There was no evidence of erosions or ulceration in the upper intestinal tract of either dog after daily injections for 43 days.

The experiments with the histamine beeswax injection and with the Roux short circuiting procedure showed that animals with the double barrel anastomosis were less prone to develop postoperative jejunal ulcer than animals with the usual single loop anastomosis. Other possible advantages of the double lumen

From the Department of Physiology, University of Oregon Medical School and the Emanuel Hospital, Portland, Oregon.

ana tomosis encouraged us to apply this method in a few selected cases in which the patients were suffering from carcinoma and from peptic ulcer.

CASE 2. H-5433 C. S., male, aged 72 years was admitted on December 11, 1946. This patient was first ill for 15 months elsewhere for 3 years. He complained of epigastric distress which had started about 5 years prior to admission. He had been unable to retain any food for 1 month and had lost 40 pounds in weight.

Examination revealed a severely emaciated and weak individual who was unable to walk without assistance. There was a movable tumor about 6 centimeters in diameter to the right of the midline in the upper abdomen. There was nutritional edema. At this patient was prepared for intra-venous injection of amino acids, glucose, and normal saline preparation and abdominal exploration was performed.

At operation on December 10, 1946 there was a dilated tumor at the lesser curvature of the stomach which had penetrated into the pancreas. There was evidence of metastases. The abdominal cavity contained approximately 500 cubic centimeters of yellow-colored fluid. The tumor mass of more than 4.5 of the stomach was removed. Retrocolic ana tomosis between the small gastric remnant and jejunum was made by the double barrel method. After operation there was no bile in the gastric suction bottle at any time. Convalescence was uneventful. The patient has gained 55 pounds in weight and employed as a laborer. He tolerates all food and has no postprandial distress (Fig. 1).

CASE 3. H-00956 M. D., male, aged 56 years was admitted on March 11, 1947. He complained of epigastric distress and pain which had started about 3 months before admission to the hospital. There was a weight loss of 20 pounds. Roentgenographic findings were negative. Gastroscopic examination revealed an ulcerating tumor mass which was about 5 centimeters in diameter and was located on the anterior gastric wall proximal to the re-entrant angle surrounding the mass the gastric wall was rigid and inflamed.

At operation on March 13, 1947 a solid tumor mass was revealed about 5 centimeters in diameter on the anterior wall of the transverse stomach. The lesser omentum contained a solid oblong mass 5 centimeters long and 5 centimeters thick. There was no metastases to the liver or greater omentum. The mesentery of the jejunum was stuffed with enlarged firm lymph nodes. The gross appearance of the tumor was that of lymphosarcoma. The mesentery and more than 4.5 of the gastric tissue were removed. A small gastric pouch was anastomosed to the jejunum by the double barrel procedure. At the final examination confirmed the gross appearance of the tumor as that of lymphosarcoma.

The patient's course was uneventful. There was no bile stained drainage in the gastric suction bottle at any time after operation. He has had a ray treatment since his discharge. There has been no weight gain. He is on a liberal diet but complains occasionally of nausea (Fig. 2).

CASE 4. H-9150 L. M., male (physician) aged 82 years was admitted on April 6, 1947. This patient complained of epigastric pain and dyspepsia of 5 months' duration. He forced himself to vomit in order to obtain relief. He had lost about 10 pounds in weight. At the age of 30 similar attacks of severe gastric pain and distress had been experienced.

Roentgenographic examination revealed a constant distention in the distal half of the stomach with 5 hour retention of most of the barium.

At operation on April 10, 1947 more than 1/2 of the gastric tissue was removed including tumor mass about 4 centimeters in diameter situated on the posterior wall of the stomach about 3 centimeters proximal to the pylorus. The stomach walls were thick and edematous. Antecolic gastrojejunostomy was made with a long double barrel jejunojejunal pouch.

He had partial gastric retention for 4 or 5 days after the gastrectomy but in spite of the retention gastric contents were not bile stained. Since discharge he has gained more than 20 pounds in weight. He follows no dietary restrictions and has no postprandial complaints (Fig. 3).

CASE 5. H-91343 O. R., female, aged 51 years was admitted on April 2, 1947. This patient was admitted complaining of pain and epigastric distress and vomiting of 5 or 6 years duration. Roentgenographic examination revealed retention of 1/2 of the barium after 3 hours with absence of peristaltic waves. Malignancy could not be ruled out as the cause of the pyloric obstruction.

At operation on April 7, 1947 there was a scarred and deformed duodenal cap with ulceration. About one half of the gastric tissue was removed. Retrocolic gastrojejunostomy was performed by the double barrel method. After operation the gastric contents in the drainage bottle were not bile stained at any time. At the present time the patient is symptom free and has gained 30 pounds in weight (Fig. 4).

CASE 6. H-91102 S. B., male, aged 63 years was admitted on March 26, 1947. He was first seen in August, 1945 at which time he gave a history of distress, gastric pain in the upper abdomen and some difficulty in swallowing. He had a frequent urge to move his bowels. A diagnosis of carcinoma and carcinoma of the rectum was made. The esophagus was dilated by bougienage. Abdominal perineal resection in one stage was performed November 10, 1945.

At operation on April 1, 1947 an ulcer was found on the posterior wall of the stomach near the cardia. There was edema and induration of the anterior and posterior wall of the stomach. About 5/6 of the

gastric tissue was removed. The lesser curvature of the stomach near the cardia was inadvertently opened and after it was repaired the remaining gastric pouch was narrowed. The terminal gastric stoma was enlarged along the greater curvature side. A retrocolic gastrojejunal anastomosis was made by the double barrel procedure. There were no bile stained secretions in the gastric suction bottle. He made an uneventful recovery and has gained about 12 pounds in weight. Although he has no difficulty eating, a roentgenographic examination reveals a dilated esophagus with delayed entry of barium at the cardia (Fig 5).

THE BRAUN ENTEROENTEROANASTOMOSIS AND THE DOUBLE BARREL GASTROENTEROANASTOMOSIS

Braun introduced the enteroenteroanastomosis in 1892 as a supplementary procedure to gastroenterostomy and to Billroth II gastrectomy. The Braun enteroenteroanastomosis gained rapid popularity because of its promise to forestall gastric retention.

In the presence of a clear passage either at the proximal or distal extremity of the gastroenterostomy, a functioning enteroenteroanastomosis could be relied upon to prevent gastric stasis. With complete blockage at both extremities of the gastric stoma, a functioning enteroenteroanastomosis would provide no relief for gastric retention. The Braun procedure proved less successful when performed in the postoperative period for the relief of a well established gastric stasis. Nevertheless it is not without merit as a prophylactic and supplementary procedure in operation for gastric malignancy. However the double barrel anastomosis functions as an enteroenteroanastomosis and in addition provides more assurance for a free passage for the gastric contents than does the standard single lumen anastomosis. The double barrel procedure embodies the enteroenteroanastomosis of Braun and a gastroenteroenteroanastomosis in a single anastomotic maneuver without a break in continuity.

Gastric evacuation in the early postoperative period following the Billroth II gastrectomy is accomplished largely by hydrostatic pressure. The anatomical relationships between the gastric pouch and the jejunum are under the control of the operating surgeon. These relationships determine the mode of

evacuation of the gastric contents. Except for the transitory stasis in the proximal duodenal loop and in the gastric pouch serious retention is nearly always due to improper and careless technique. Only in a case of reoperation are there occasionally presented reconstructive problems with technical difficulties not under the complete control of the operating surgeon. In my early experience with the gastrectomy operation exploration was carried out in 2 patients because of gastric ileus. There is reason to believe that these 2 patients would have recovered without additional surgery as did 2 other patients who developed gastric retention. In my last 350 consecutive gastrectomies for ulcer or carcinoma reoperation because of gastric retention was not necessary in any case.

Even under the most favorable conditions it is more difficult to assure the emptying of the gastric contents following a gastroenterostomy than after a Billroth II type of gastrectomy. In the presence of the pylorus and the muscular transverse stomach (antrum) the anatomical relationships after gastroenterostomy cannot always assure the emptying of gastric contents through the gastroenterostomy stoma by simple hydrostatic pressure. When gastroenterostomy is performed in the presence of a dilated atonic stomach evacuation is impaired to a greater degree. Under these conditions a double barrel gastrojejunostomy with a large stoma should have a much better chance of assuring the emptying of the gastric contents than the standard type gastroenterostomy (Fig 6). The performance of the double barrel anastomosis require more time than performance of the standard single loop gastrojejunal anastomosis. Edema and infection because of a faulty suture technique, torsion of the anastomosis or a thick mesocolon attached in the immediate vicinity of the anastomosis will prove equally disastrous for any type of gastroenterostomy or gastrectomy. A malfunctioning stoma is largely the result of either insufficient experience or the lack of supreme diligence.

Transitory stagnation from postoperative inertia takes place after any type of gastric operation. Inertia and partial stagnation

should be prolonged after the double barrel anastomosis because the newly fashioned inert jejunal sacculum and the gastric remnant empty through hydrostatic pressure and gravity due to change in the patient's position. The important consideration however is the assurance of a wide and unobstructed passage which gives the double barrel anastomosis a long term advantage over the standard type anastomosis. Initial stagnation is effectively controlled by the Wangensteen method of continuous lavage.

No serious gastric retention resulted in the 25 patients operated upon by the double barrel jejunal lumen anastomosis. It was necessary to introduce a Levine tube twice in one patient on the fifth postoperative day. In another patient in whose case antecolic gastrectomy was performed the jejunojejunal anastomosis was unusually long. The patient complained of nausea and fullness for about 5 days following the operation. Gastric emptying was not complete and was relieved by periodic lavage. The patient began to take nourishment on the third postoperative day.

REFLUX OF GASTRIC CONTENTS INTO THE AFFERENT ENTERIC LOOP REGURGITATION OF BILE AND PANCREATIC JUICE INTO THE STOMACH VOMITING OF BILE. GASTRITIS THE POST GASTRECTOMY SYNDROME

Hofmeister's modification of the Reichel Polya gastrectomy consists of partial closure of the cut end of the stomach at the lesser curvature. This technique gives more security to the gastrojejunal anastomosis at this angle. Finsterer popularized the Hofmeister modification. He laid particular emphasis on the prevention of reflux of the gastric contents into the proximal jejunum and into the duodenum by cutting the stomach in a line parallel to the direction of the esophagus, and by the formation of a spur at the lesser curvature. Finsterer feared that reflux of gastric contents into the duodenum would jeopardize the duodenal closure. Finsterer who first introduced the exclusion reaction for duodenal ulcer also reasoned that the back flow of the gastric contents into the pyloric remnant through the open pylorus presented a predisposing factor to jejunal ulceration. It is unlikely that back

flow of gastric contents into the afferent loop could be the cause of a blowout of the duodenal stump. Either a stenosis at the proximal angle of the anastomosis or most commonly the faulty technique of duodenal closure, is responsible for the leakage from the duodenal stump.

The reflux of gastric contents into the proximal jejunum and duodenum is desirable because of the enhanced production of secretin and the alkaline pancreatic juice which should prove to be an additional safeguard in the prevention of jejunal ulcers and also an aid in intestinal digestion. There seems to be no valid objection to the reflux of gastric contents into the proximal loop provided that these contents are prevented from regurgitating back into the gastric pouch. The degree of regurgitation of the intestinal contents back into the stomach depends on the technique of the gastrectomy operation. A. B. Watson recently reviewed the end results of 132 gastrectomies and reported 12 cases of patients who vomited bile. Two of my own patients have had antecolic gastrectomies performed elsewhere with a long afferent jejunal loop attached to the greater curvature angle. These patients have complained of frequent vomiting of bile. Some of the dyspeptic complaints after the Finsterer-Hofmeister operation result from an unpredictable variation in the technique which allows an excessive amount of bile and pancreatic juice to enter the gastric remnant. Alkaline duodenal contents regurgitating into an empty stomach may cause irritation and inflammation of the gastric mucosa. A few of my patients complain of a "bitter stomach" and anorexia at breakfast time. The extent of the regurgitation of the alkaline duodenal contents into the gastric remnant may conceivably be the answer to some of the disappointing results of the gastrectomy operation which some consider to be related to postoperative gastritis.

Cure of the original ulcer and prevention of jejunal ulcers are considered in part to depend on the regurgitation of bile and the alkaline pancreatic juice into the stomach. Boldyreff thought that regurgitation of bile and pancreatic juice into the stomach is a normal process which serves to regulate and maintain

Fig 1

Fig 3

Fig 4

Fig 5

Fig 1. Case 2. Roentgenogram taken 8 months after gastrectomy for carcinoma. The gastric remnant extends no more than about 3 centimeters beyond the cardia. The double barrel saccululation has enlarged since the operation.

Fig 2. Case 3. Roentgenogram taken 2 months after gastrectomy for lymphosarcoma. Only a small gastric remnant is left. The double barrel anastomosis is long and narrow.

Fig 3. Case 4. Roentgenogram taken about 1 year after antecolic gastrectomy for a carcinoma of the stomach. The

faint shadow between the gastric remnant and the large jejunal saccululation shows valve-like formation at the gastrojejunal stoma.

Fig 4. Case 5. Roentgenogram taken about 1 year after gastrectomy with double jejunal lumen anastomosis for duodenal ulcer with obstruction.

Fig 5. Case 6. Roentgenogram taken about 1 year after gastrectomy with double jejunal lumen anastomosis. Minimal gastric remnant with only a few flecks of barium shadow showing.

gastric acidity at a constant level. Authi Kesavalu and Frank Mann concluded that the presence of even the entire duodenal contents in the stomach does not cause effective neutralization, buffering and dilution of gastric acidity in either the fasting or the digesting state. It is questionable if the slight and

infrequent duodenal regurgitation that occurs normally can be a primary and essential factor in controlling intragastric acidity. (Authi Kesavalu and Frank Mann). Schmilinsky conceived the idea of the formation of an inside apothecary by anastomosis of the proximal jejunal loop into the stomach thus diverting

Fig. 6. a, left. Gastroenterostomy with single loop and jejunojejunostomy. Obstruction may result from kinking of the jejunal loops, from dilated stomach compressing the jejunal loops or from a spur formation of the jejunum protruding into the lumen of the stomach. b, Gastroenterostomy with a double barrel anastomosis is less likely to result in such complications.

all of the duodenal secretions into the stomach. The Schminsky procedure increased the incidence of jejunal ulcers in the experiment and in the clinic (Lannin Wangenstein). Cholecystogastrostomy proved equally disappointing (Braithwaite). All the operations which introduce alkaline duodenal contents into the stomach produce irritation, gastritis, anorexia, nausea and vomiting. Consequently it is not undesirable to have a reflux of the gastric contents into the afferent jejunal loop and into the duodenum provided this precludes the entrance of the intestinal contents back into the gastric pouch.

Gastric contents in the drainage bottle usually become bile-stained on the second postoperative day following the conventional Hofmeister Finsterer gastrectomy. Apparently the absence of bile-stained contents in the Wangenstein drainage bottle in the first or second day is due either to paresis of the duodenum or to partial suppression of its secretion.

There was no bile-stained gastric secretion in the drainage bottle in 24 patients with the double barrel anastomosis at any time after operation. Apparently intestinal contents failed to enter the gastric lumen. The degree of regurgitation of intestinal contents into the stomach will depend on the chance position and the length of the jejunojejunostomy anastomosis. The creation of a double lumen sac produces a redundancy of the jejunal wall which allows a generous overlapping over the gastric wall. This technique fashions a valve-like protrusion of the gastric stoma into the

Fig. 7. Diagram of gastrectomy with double barrel jejunal anastomosis for jejunal ulcer. The artist failed to depict partial closure of gastric stoma at lesser and greater curvatures. Inset, valve-like formation of the gastrojejunal anastomosis.

jejunal sacculum which prevents the entrance of the intestinal contents into the stomach. Thus, the mechanical component of the double barrel gastrectomy will assure the desirable effects of reflux of gastric contents into the proximal jejunal loop and duodenum and at the same time prevent entrance of alkaline duodenal contents back into the stomach (Fig. 7).

There are a number of symptoms and disabilities which take place in some patients following the gastrectomy operation. Only those complaints will be considered which are not related to the presence of a jejunal ulcer. It is difficult to explain why the greatest majority of the patients are either completely or tolerably free of postoperative disabilities while others are definitely annoyed by them. Though nearly all of the more than 400 gastrectomies performed by the author for peptic ulcer were carried out by a standard technique it is conceivable that some of the complaints after operation were due to an un-

Fig. 8. Total gastrectomy with a double barrel esophagojejunal anastomosis. a, left, The anastomosis completed. The anchoring sutures of the jejunum to the diaphragm are not shown in this illustration. b, Window in the anterior wall of the completed double barrel anastomosis to demonstrate valve-like formation

predictable variation in technique permitting too much reflux of intestinal contents into the stomach. In a recent publication the writer has analyzed some of the technical variations of the Billroth II gastrectomy which are likely to result either in jejunal ulceration or in postoperative disabilities not related to jejunal ulcer. Attention was called to disabilities following the Schmilinsky operation gastrectomy with the proximal jejunal loop joined to the greater curvature angle of the anastomosis and also following creation of a long proximal jejunal loop placed either at the lesser or at the greater curvature angles of the gastrojejunal anastomosis. It was reasoned that such variations in the operative technique of the Billroth II operation permit regurgitation of the alkaline enteric contents into the gastric pouch causing nausea, anorexia and vomiting. The severity of the symptoms caused by reflux of intestinal contents will largely depend on the extent of regurgitation into the stomach. In the Hofmeister Finsterer operation a variable part of gastric wall along the lesser curvature is invaginated into

the gastric lumen. This tumor like formation receives the impact of the enteric contents from the proximal loop which in part may be propelled directly into the distal jejunal loop without entering the stomach. Closure of the gastric stoma along the lesser curvature angle also creates a smaller gastrojejunal opening than in the original Reichel Polya operation. The freedom from nausea, anorexia and vomiting in by far the greatest majority of my own gastrectomized patients is evidently the result of mechanical factors inherent in the technique of the gastrectomy operation. Though there have been several patients complaining of nausea and anorexia and also an occasional patient reporting one or two vomiting spells soon after leaving the hospital, I have no knowledge of any of my gastrectomized patients ever complaining of frequent vomiting.

The favorable results are at variance with the experience of others. Schindler's clinical and gastroscopic studies on the postoperative stomach are extremely discouraging. He reports a great number of patients who are not

relieved of pain by surgery and who do not return to the surgeon who performed the operation but consult others.

In some hospitals there are a really terrifying number of such patients observed who after gastric surgery had become permanently incapacitated (Schindler). The observation was made that their distress proved to be almost intractable. Schindler was the first to describe the frequency of severe gastritis in the postoperative stomach. He observed that when there were rhythmical pyloric like activities of the artificial stoma there was no evidence of gastritis. Schindler agrees with others that the gravity, the extent and the various forms of gastritis in the postoperative stomach impressively exceed all other pictures of inflammation (Gutzeit and Teitge).

From the grandiosity of these changes alone and without knowledge of the case history and of the clinical findings it is possible to recognize the postoperative stomach (Gutzeit and Teitge). Schindler concludes thus: "the unregulated reflux of intestinal juice through a patent stoma is the chief reason for the origin of the chronic inflammation of the postoperative stomach and that operations which do not prevent this reflux cannot be considered as proper treatment for an essentially benign disease such as peptic ulcer."

Again quoting from Schindler there is a saddening unanimity of opinion that treatment of the gastritis of the postoperative stomach is one of the most hopeless tasks. The symptoms of postoperative gastritis are characterized by torturing continuity and intractability.

Personal experience with the gastrectomy operation for peptic ulcers over a period of 24 years has been most gratifying. Only a few patients are annoyed and partially incapacitated. Postgastrectomy complaints and disabilities do not always follow a similar pattern. At times it is difficult to elicit any definite symptoms. The patient simply states that all is not well. Weakness, fatigue, dizziness, and a fleeting feeling of faintness are frequent complaints. The inability to gain weight is resented by many patients. Some patients have ravenous appetites while others com-

plain of anorexia. There may be a bizarre tolerance to highly seasoned foods such as pickled herring, onions, etc. and an intolerance to milk and pastries. The postprandial feeling of fullness and rapid pulse and perspiration usually disappear after lying down. These symptoms are thought to be brought about by an overdistended gastric pouch or from the precipitous emptying of the gastric contents into the jejunum "dumping syndrome" also causing overdistention of the jejunum and initiating a splanchnic reflex. The relief brought about by a recumbent position is considered to be due to slowing of gastric evacuation. Absorption of sugar from the precipitous emptying of the gastric pouch is also considered to be related to symptoms characterized by dizziness, fleeting faintness and occasional syncope. Though I have seen many patients in my office with postgastrectomy complaints, none have had symptoms which were severe enough to require hospitalization. It is not improbable that some of these patients have sought relief for their complaints elsewhere.

The nature of some of these postgastrectomy symptoms is not well understood and it is inconceivable that all of them can be explained on the basis of gastritis due to reflux of enteric contents into the gastric pouch. While it is reasonably certain that a double barrel anastomosis will be effective in preventing the regurgitation of bile and pancreatic secretion into the stomach it is too early to appraise this operation in relation to the postgastrectomy symptoms not related to the reflux of enteric contents into the stomach. One may be permitted a hopeful speculation that the double barrel jejunal saccululation may also act as a buffer causing a retardation of the jejunal evacuation.

THE TECHNIQUE OF THE DOUBLE BARREL OPERATION AND ITS SPECIAL INDICATIONS

The double barrel procedure can be applied in any variation of the Billroth II gastrectomy, total gastrectomy or gastroenterostomy. The completed anastomosis with the flaring of the afferent and efferent bowel loops from the crotch of the newly created saccululation resembles a pantaloons garment in its appearance.

Fig. 9. The technique of the gastrectomy operation with a jejunojejunal anastomosis. a, Two jejunal loops sutured together. The proximal loop should be longer than is shown. b, The first seromuscular suture completed along posterior wall. An opening, not shown, is first made in jejunal wall at jejunal bend and close to mesentery. The jejunal loops are flared open. c, The beginning of second row of through and through continuous hemostatic suture for posterior wall. d, The hemostatic sutures for the posterior wall close to the mesentery completed. e, First continuous sero-

muscular stitch completed to approximate the anterior jejunal walls. Interrupted silk sutures between posterior gastric wall and posterior wall of jejunal sacculculum. f, The double barrel jejunal anastomosis completed. The artist sketched this operation during a double barrel gastrectomy in which the whole gastric stoma was utilized for the gastrojejunal anastomosis. In most of these gastrectomies a part of the gastric stoma along the lesser curvature is closed.

Fig. 5. Diagram of antecolic double barrel anastomosis. a, Cross section showing the valve like formation at the stoma.

In the first double barrel gastrectomy performed for a duodenal ulcer in 1943 the anterior suture line of the double lumen jejunal sacculation was anastomosed to the greater curvature angle of the gastric remnant. This technique was also used in experimental animals with good functional results. In 1 gastrectomy the anterior suture line of the jejunal sacculation joined at the center of the anterior wall of the gastric stoma.

The efferent and afferent loops of the jejunum are joined in an antiperistaltic direction by interrupted sutures close to the mesentery in order to prevent the protrusion of a large mucosal fold into the lumen at the jejunal bend. The jejunal walls flare wide apart at the jejunal bend permitting a wide approximation between the jejunum and stomach. The gastrojejunal stoma is made to protrude into the jejunal sac in a valve like fashion which aids in preventing regurgitation of intestinal contents into the stomach. After completion of the anastomosis both jejunal loops are approximated to each other by a few sutures distal to the crotch of the pantaloon seat in order to prevent possible intussusception of the proximal jejunal loop into the sacculation.

In the operation for jejunal ulcer the old jejunal stoma may be reconstructed to fit into a double barrel type of anastomosis (Fig. 7).

The double barrel type of anastomosis is particularly adaptable in gastrectomies for

ulcers near the cardia and for carcinoma when only a small fragment of gastric tissue is left or when the stomach is removed *in toto*. This type of anastomosis makes possible a wide area of serosal approximation without producing a stenosis. It prevents regurgitation of the intestinal contents into the stomach or into the esophagus and creates a large jejunal cavity acting as a substitute stomach.

In Case 6 a large ulcer was found on the lesser curvature near the cardia. This ulcer produced induration spreading along the anterior and posterior walls toward the greater curvature. After removal of most of the stomach there was only about 1 centimeter left of the lesser curvature near the cardia and only about 6 centimeters of the greater curvature. The lesser curvature was reconstructed by pulling in, and folding of the anterior and posterior stomach walls over the esophagus. The gastric remnant presented a short tubular bowel like structure with a tumor-like protrusion of the reconstructed lesser curvature into the gastric lumen. The gastric stoma measured no more than about $1\frac{1}{2}$ centimeters. A standard gastrojejunal anastomosis would have resulted in an inadequate stoma. Because of the swollen and inflammatory gastric walls considerable inversion was required to assure a safe gastrojejunal anastomosis. Too much suturing in a standard type of anastomosis results in kinking of the jejunum at the proximal and distal angles of the stoma endangering a free passage for the gastric contents. A small gastric pouch with a narrow gastrojejunal stoma also favors regurgitation of the gastric contents into the esophagus. Consequently the double barrel technique appeared to have definite advantages in this particular case. The gastric stoma was enlarged by a generous incision of the gastric wall along the greater curvature. The enlarged gastric stoma was anastomosed to the jejunum by the double barrel technique. Since operation the patient has gained 20 pounds and follows no dietary restrictions (Fig. 5).

In another patient 72 years old, nearly the whole stomach was removed including the omentum because of carcinoma, and the operation performed in a similar manner. He later developed a very large jejunojejunal pouch a

substitute stomach (Fig 1) He has gained 55 pounds in weight He is symptom free and adheres to no dietary restrictions and is working as a laborer In cases of a total gastrectomy the terminal part of the esophagus can be incorporated into the double barrel jejunal sacculum without danger of stenosis or obstruction at the proximal or distal angles of the esophagojejunoanastomosis because of too much inversion It makes for a safer anastomosis and creates a valve like structure which allows for a free passage for the esophagus without the possibility of regurgitation from the intestine into the esophagus (Fig 8) The esophagojejunal anastomosis requires a great deal of attention and diligence and is more time consuming than the standard procedure Wide Halstead sutures should be avoided because they have a tendency to narrow the esophageal stoma.

SUMMARY AND CONCLUSIONS

A variation of gastrojejunal anastomosis utilizing a double barrel jejunal loop is presented This double barrel jejunal anastomosis embodies a Braun enteroenteroanastomosis and also a gastroenteroanastomosis in a single anastomotic procedure and without a break in continuity It prevents stasis in the afferent enteric loop and precludes an obstruction either at the proximal or the distal angles of the gastrojejunal anastomosis.

A double barrel method of gastrojejunal anastomosis was first introduced by the writer in 1934 as an experimental procedure in the studies on the etiology of postoperative jejunal ulcers.

A gastrectomy with a double barrel anastomosis was first applied in a patient with a duodenal ulcer in 1943 and later in 24 more patients with carcinoma and also with simple ulcer

Thus far the clinical results of the operation are exceptionally favorable Most of the patients have gained weight and are free from the postgastrectomy symptoms which are not infrequent after the standard single loop gastrectomy

The gastrectomy with the double barrel jejunojejunal anastomosis, because of the enteroenteroanastomosis and the valve-like for

mation of the gastrojejunal stoma prevents the entrance of the intestinal contents into the stomach The continuous reflux of intestinal juices into the gastric remnant results in severe gastritis anorexia, nausea and vomiting causing chronic disability

The double barrel gastrectomy has definite advantages in operation for carcinoma and for gastric ulcer and particularly in the presence of a minimal gastric remnant Because of the abundance of the intestinal wall from the jejunojejunal anastomosis a wider area of gastrojejunal approximation is permissible without endangering a free passage from the gastric pouch In addition a large jejunal sacculum is also formed which may compensate for the small capacity of the gastric pouch Roentgenographic examination of patients several months after operation shows that the double lumen sacculum enlarges with time

The double barrel procedure is recommended for a total gastrectomy for establishment of the esophagojejunal continuity It prevents regurgitation of the intestinal contents into the esophagus and creates a large storage space, a substitute stomach

Though it is apparent that the jejunal ulcers can be largely prevented by a properly performed radical standard gastrectomy the latter cannot always prevent those symptoms which are dependent on the reflux of the intestinal contents into the stomach

Thus far personal experiments with the Y anastomosis of Roux and with the injection of histamine in beeswax yield some evidence that the double barrel anastomosis is possibly less prone to jejunal ulceration than the single standard procedure Nevertheless the wider application of the double barrel gastrectomy for the treatment of duodenal ulcers will await more intensive experimentation in order further to evaluate its ability to protect the animal against the jejunal ulcer

The double barrel anastomosis should instill caution and reserve commensurate with a procedure which is unconventional The success of the procedure requires more time and diligence than is required in the performance of the established operation Rehearsal on the cadaver and in the experimental laboratory will enable the surgeon to uncover details and

safeguards in the technique which he may not discern in the written page

Since this article was accepted for publication an additional 7 gastrectomies were performed by the pantaloons method. The results are most reassuring.

THE CERVICAL STUMP

An Analysis of 123 Cases

JOSEPH B CRAWFORD M.D., Chattanooga, Tennessee, CONRAD G COLLINS M.D., M.S. F.A.C.S.,
and JOHN C. WEED M.D., M.S., F.A.C.S., New Orleans, Louisiana

ALTHOUGH the medical literature is replete with articles on carcinoma of the cervical stump there is a paucity of reports concerning the other pathologic changes occurring in this organ. Since we have seen a great number of patients complaining of symptoms referable to the cervical stump which were not relieved by previous pelvic operations a critical analysis of all such cases of patients admitted to the Ochsner Clinic and Charity Hospital of Louisiana at New Orleans from January 1931 to July 1947 was undertaken in an effort to elucidate the other heretofore little discussed pathologic processes. There were 123 patients in whom the cervical stump was removed during this 16½ year period not including the innumerable patients with a cervical stump in whom symptoms were relieved by simple cauterization.

Forty or almost one-third of the patients in this series (32.5 per cent) had the same complaints for which the original pelvic operation had been performed. Of these 40 patients 23 had been subjected to only one operation—supravaginal hysterectomy usually combined with appendectomy. The other 17 had a supravaginal hysterectomy bilateral salpingo-oophorectomy and appendectomy performed at various laparotomies. In these 17 cases although the entire internal female genitalia with the exception of the cervix had been removed the cervix was never recognized as the organ responsible for the symptoms.

SYMPTOMATOLOGY

The most frequent complaints in this series are listed in Table I. Multiplicity of com-

Abstract of thesis submitted by Dr. Crawford to the faculty of the Graduate School, Tulane University, Louisiana, in partial fulfillment of the requirements for the degree of Master of Science in Gynecology and Obstetrics.

From the Departments of Obstetrics and Gynecology, Tulane University of Louisiana School of Medicine, Tulane Unit, Division of Obstetrics and Gynecology, Charity Hospital of Louisiana at New Orleans, and Department of Gynecology and Obstetrics, Ochsner Clinic, New Orleans.

plaints was of course the general rule. The commonest complaint was pelvic pain which occurred in 53.6 per cent of cases. This was described as lower abdominal pain involving either one or both sides of the iliac fossa usually chronic in nature rather ill-defined often worse just prior to the onset of the menstrual flow and aggravated by walking around or lifting heavy objects. Bearing down sensations occasionally accompanied this pain. Although the pain often simulates that caused by chronic diseases involving the lower abdominal organs such as adnexal disease chronic appendicitis or diverticulitis one of the commonest causes of it is a chronically diseased cervix. Sir James Young in 1930 was the first to recognize this important cervical lower abdominal pain relationship and to call attention to the diagnostic significance of a clinical procedure for reproducing the patient's symptoms. This test has failed to attract physicians in this country. The only references to it in the American medical literature have been by Holloway who in 1936 emphasized the importance of reproducing the patient's symptoms by applying tincture of iodine or silver nitrate to the cervix and by one of us (C. G. C.) who in 1938 again directed attention to reproduction of pelvic pain on motion of the cervix. A review of all current gynecologic textbooks reveals no reference to reproduction of pelvic pain which is caused by a diseased cervix. This is probably one of the reasons that erroneous diagnoses are made and that many of these patients have been subjected to needless or incomplete operative procedures.

The following clinical test has proved of great help in determining the part the cervical stump plays in the patient's symptoms. The examining fingers should first be inserted into one lateral fornix and the cervix pushed to the opposite side of the pelvis. For example if

TABLE I.—SYMPTOMS

	No. cases	Per cent

Stricture	5	10.2
Fibroids	3	6.2
Total	49	99.9

the pain is on the right side the cervix should be pushed to the left with resultant tension on the right cardinal ligament and vice versa. The patient should then be asked not only

Does this hurt? but Is this the same pain of which you complain? A healthy cervix may be displaced considerably in all directions without discomfort and even maximum displacement, though uncomfortable, does not cause actual pain. However any attempt to displace a diseased cervix at once provokes the symptoms of which the patient complains. In the absence of palpable masses in the adnexa if lower abdominal pain can be reproduced in this manner one may be certain that the pain is cervical in origin. Reproduction of symptoms by placing stress on the base of the broad ligaments is probably due to the lymphatic drainage of the cervix, with concomitant mild or severe lymphangitis.

The second most frequent complaint in this series was profuse leucorrhoea, which is one of the most difficult of all pelvic complaints to evaluate. Most women believe that a certain amount of vaginal discharge is normal. All patients in this series complained of a leucorrhoeal discharge in addition to other symptoms. Sixty or 48.7 per cent complained of a discharge profuse enough to require daily douches or wearing of pads and all had this same complaint before supravaginal hysterectomy.

Forty-nine patients had a bloody vaginal discharge, 17 of whom complained only of bleeding following coitus or douches. The remaining 32 patients had an intermittent bloody vaginal discharge occurring without obvious trauma. The principal pathologic lesions in these cases of posthysterectomy bleeding from the cervix are shown in Table II. The chief cause was severe chronic cervicitis with erosion which constituted 42.8 per cent of the total. This was closely followed by polyp, carcinoma, endometriosis, stricture, and fibromy-

omas in the order named. Five patients had sufficient functional endometrial tissue to explain the bleeding.

Seven patients (14.3 per cent of the total number of cases) who complained of bleeding had carcinoma. This is a much lower incidence than the 46 per cent reported by Davis and Cheek.

Thirty-nine patients complained of deep-seated dyspareunia. This seemingly high incidence is probably relative though it exceeds that of most previous reports. Many patients are reluctant to admit having this symptom. If the patient is asked directly and tactfully she will admit with little or no embarrassment that this is the real reason for her consultation. Few volunteered this information but most admitted with great relief that though they had consulted many physicians in the past, this had been the first time that the question of painful coitus had ever been mentioned. Thirty-five of these patients had this same symptom prior to the original operation. Failure to relieve this symptom previously was probably due not only to lack of interrogation but also to failure to realize that a diseased cervix is a frequent cause of deep-seated dyspareunia. The pain is severe and is described as if something sore is being struck. It is often so intense as to prevent orgasm or to cause coitus to be discontinued. It may be followed by pelvic soreness or backache which may persist for 24 hours. With the exception of 2 patients who had endometriosis all these patients had moderate to severe chronic inflammatory changes in the cervical stump. Often the same pain can be reproduced by touching the infected cervix with the examining fingers or by manipulation of the indurated, uterosacral ligaments. Removal of the diseased stump was followed by complete relief in all 49 patients.

Low backache was a complaint in 28 per cent of cases. Although lumbosacral pain is one of the commonest complaints of women the diseased cervical stump can be implicated by a simple clinical test. Backache originating from a diseased cervix is usually localized in the sacral and coccygeal areas. It is aggravated just before or during the menstrual flow, by lifting a heavy object or by exertion and is relieved by reclining. It may be exacerbated during defecation. Existing concomitantly with cervicitis is lymphangitis of the uterosacral ligaments. Therefore by placing the uterosacral ligaments on stress the backache can be reproduced. This is accomplished by placing the fingers in the posterior fornix and lifting the cervix anteriorly. In a normal cervix this maneuver causes little or no distress. Removal of the cervical stump resulted in complete relief of this type of backache in all cases in this series.

In 1933 White was able to demonstrate experimentally that tubercle bacilli and India ink particles in the lymphatic channels of the bladder in animals were destroyed from 1 hour to 3 weeks following injection of these foreign materials into the cervix. He concluded that cervicitis is a constant companion of cystitis and that any attempt to treat cystitis or trigonitis is doomed to failure unless the neglected cervix is also treated. His observations have been confirmed by subsequent clinical investigations. Most urologists now realize this relationship and 4 of the patients in this series were referred directly by them. Discomfort in the urinary tract usually dysuria and frequency was a complaint in 32.5 per cent of cases. In cases with a coexistent cystocele or urethrocele stress incontinence of urine was noted. Some patients had been treated unsuccessfully for cystitis by local applications of silver nitrate and frequent soundings whereas upon removal of the infected cervical stump the urinary symptoms completely disappeared. It is also entirely possible that the diseased cervical stump may be the focus of recurrent pyelonephritis although there were no such cases in this series. The offending organism could conceivably reach the renal pelvis by way of the lymphatic channels of the bladder and the perireteral lymphatics. This focus

should never be overlooked as the original site of recurrent "pyelitis" in women.

Twenty-one patients complained of a bearing down sensation in the lower portion of the abdomen which was described as feeling as if the organs were falling out. This was always aggravated by any activity, such as being up and about on the feet, extended walks, lifting heavy objects, coughing, straining at stool, or by any condition which would tend to increase intra abdominal pressure. Fourteen of these 21 patients had a third degree prolapse of the cervical stump and the remaining 7 had second degree prolapse. Those who advocate supravaginal hysterectomy contend that one advantage of the procedure is that the cervix aids in support of the vaginal vault a fact difficult to accept in the light of these figures. It is an easy matter to determine if the prolapsed stump is causing the patient's symptoms. One merely places a tenaculum on the posterior lip of the cervix and gently pulls downward. If this reproduces the same bearing down sensation then prolapse of the stump is causing the symptoms.

PATHOLOGY

The various pathologic processes noted in this series are listed in Table III. It is not meant to imply that such a high percentage of disease occurs in all cervical stumps, but it should be re-emphasized that these figures were obtained from cervixes which were considered sufficiently diseased to warrant surgical extirpation. It is unfortunate that the total number of patients with a cervical stump who were examined over the same period of years or the number who had pelvic complaints and were relieved by simple office cauterization is not available. We estimate that approximately 20 per cent of these patients required cauterization or surgical treatment. It is also regrettable that records of the previous surgical treatment were unobtainable. From these records could have been determined what treatment if any had been directed toward the cervix at the time the fundus was removed and the effect of such treatment on the subsequent clinical course.

It is apparent from Table III that multiplicity of lesions was the rule. For example

TABLE III — PATHOLOGY

	No. cases	Per cent
Chronic and chronic subcervicitis	0	82.9
Leucorrhea	3	26.9
Empyema	5	4
Polyps	20	6.3
Endometriosis	5	4
Fibroids	4	3
Epidermoid carcinoma	7	5.7
Granuloma		8

cervical polyps were frequently accompanied by severe chronic cervicitis and pyocervix was always associated with cervical stenosis. In 10 patients or 82.8 per cent the pathologic report was chronic cervicitis or chronic cystic cervicitis. In 52 cases it was the only lesion noted. In the remaining cases also present were polyps strictures prolapse and other pathologic processes which indubitably played a role in the production of symptoms. Of the 2 patients in whom infection alone was noted the order of frequency of symptoms was pelvic pain dyspareunia, leucorrhea abnormal bleeding urinary difficulties and backache. It is noteworthy that 22 or 43 per cent of the group had had a previous supravaginal hysterectomy to correct the complaints from which they obtained no relief until the cervical stump was subsequently removed. It is thus obvious that incomplete or unnecessary surgical procedures had been performed because of failure to recognize the important role the cervix plays in the symptomatology of pelvic disease. It is hoped that the clinical tests discussed under symptomatology will enable the physician to make a more positive diagnosis of pelvic lesions and thereby prevent such mistakes in the future.

Thirty-two patients had stenosis of the cervix. Many advocates of supravaginal hysterectomy advise routine cauterization or conization of the cervix at the time of hysterectomy. Since the patients in this series were operated on previously elsewhere, it was impossible to determine what percentage of stricture existed prior to the original operation or developed as the result of or subsequent to the operation. It is probable however that the majority developed as a result of such procedures as cauterization or conization of the cervix at the time of hysterectomy. Only 24

per cent of patients with stricture had the same complaints prior to the initial operation, in the remaining 76 per cent symptoms developed after the operation. It may be assumed then that in this latter group stricture developed as a result of some procedure on the cervix at the time of the operation. Noteworthy are the 5 cases of stricture with resultant empyema of the cervix. These 5 patients were wholly or partially disabled. Surgical extirpation of the cervical stump was followed by complete relief of symptoms and resumption of normal activity for the first time in years. Three of these patients had been running a low grade fever with arthritis or arthralgic symptoms for years. These symptoms disappeared following removal of the stump.

Twenty patients had benign endocervical polyps. As would be expected, these polyps were associated with rather severe chronic infection. Eight patients complained of post coital bleeding. This was the most frequent complaint followed closely by leucorrhea, dysuria, and pelvic pain in the order named. The average interval between hysterectomy and removal of the cervical stump in our entire series was 8.4 years. Due probably to the patient's alarm over the vaginal bleeding the interval between hysterectomy and extirpation of the cervical stump was only 6 years in the group in which polyps were the chief pathologic finding.

Since cervical endometriosis is a rather rare condition it was surprising to find endometriosis of the cervical stump in 5 cases—an incidence of 4 per cent. Goodall (7, 8) believes that cervical endometriosis is always secondary to uterine endometriosis by extension into the fibromuscular tissues of the cervix. In all these cases hysterectomy had been performed for fibromyomas. It is probable that endometriosis of the fundus or adenomyosis existed unrecognized at the time in some of these. Irregular vaginal bleeding either postcoital or without apparent cause was a complaint in all these patients. Other symptoms were pelvic pain dyspareunia, and backache in the order named. In 1 case there was a cervical fibroid in conjunction with endometriosis. In all but 2 of these cases the ovaries had been extirpated at the time of the original hysterectomy. One

patient had had previous radium castration and 1 was past the climacteric. The problem of destruction of ovarian function was therefore not encountered.

It has been estimated that cervical fibroids account for 3 to 8 per cent of all cases of fibroids encountered. Fibroids of the cervical stump are rare. Giles was able to collect only 6 cases to which Hyams added 4, making a total of 10 cases reported in the literature. There were 4 patients in this series with fibroids. These patients complained of vaginal bleeding, urinary frequency and pelvic pain in the order named. All had previously undergone hysterectomy for fibromyomas, but endometrial or myometrial tissue was preserved in all. It is believed that these cervical fibroids probably developed in the remaining myometrial tissue. Therefore retention of sufficient endometrial tissue for the preservation of menstrual function would seem to be not without some danger.

The reported incidence of carcinoma of the cervical stump has varied from 0.45 to 7.2 per cent (1, 2, 4, 8, 9, 15). The incidence of 5.7 per cent (7 cases) in this series is by no means a true incidence of the disease. It is indicative merely of the incidence of carcinoma in the 123 cases in which operative removal of the cervix was deemed necessary. Vaginal bleeding or spotting was observed in all 7 cases. Five patients complained of profuse leucorrhea and 1 of pelvic pain. In 3 cases carcinoma was diagnosed by biopsy, radium was inserted and this was followed by surgical removal. In 4 cases early carcinoma *in situ* was diagnosed and the cervical stump was removed without previous radiation. In the last 2 patients, 1 of whom complained of contact bleeding, repeated biopsies yielded normal results but after removal early epidermoid carcinoma was positively identified by microscopic studies.

Davis and Cheek believe that every patient who complains of vaginal bleeding following supravaginal hysterectomy should be subjected to a cervical biopsy and curettage of the endocervical canal. We prefer biopsy followed by surgical extirpation of the entire cervical stump.

In 1 case the biopsy report was chronic granuloma of undetermined type. This pa-

tient's chief complaint was profuse purulent leucorrhea which was accompanied by pelvic pain and by backache. Removal of the granuloma of the stump resulted in complete relief of symptoms.

TREATMENT

Prophylaxis is always an important part of treatment of any disease and is particularly significant in this condition. Since 32.5 per cent of the patients in our series had had one or more previous operations for the identical complaints for which they consulted us, it may be assumed that the causal relationship between the cervix and their symptoms was not recognized at that time. A diseased cervix should always be suspected in any woman with pelvic pain, dyspareunia, contact bleeding, backache, leucorrhea and urinary difficulties. The diagnosis may be easily established by the clinical tests already described. If hysterectomy is indicated for associated pelvic pathologic conditions, the uterus should be removed *in toto* whenever this procedure is technically possible.

Preservation of sufficient endometrium to allow the patient the privilege of menstruating has already been shown to be not only useless but oftentimes dangerous. Further more, preservation of the cervix in order to provide proper support for the vagina has also been shown to be a fallacious argument. Should it be technically impossible or not expedient to remove the cervix at the time of hysterectomy, the patient must be warned that it remains and that periodic examinations are necessary. No patient is more pathetic than the one who has been lured into a false sense of security by being told that the uterus has been removed and that she will have no further trouble only to discover years later that carcinoma or some other serious pathologic lesion has developed in the remaining cervical stump. When hysterectomy is performed on our service the entire uterus is always removed if possible. The technique used in these cases has been previously described by Tyrone and Weed (14). If the cervix is not removed at the time of hysterectomy, it is removed by the vaginal route as soon as the patient's general condition permits. This has also been the practice in large gynecologic clinics through-

out the country and more and more total hysterectomies are being performed daily. Prophylactic treatment, therefore, consists in first the diagnosis and treatment of the diseased cervix itself prior to operation and second performance of total hysterectomy whenever removal of uterus is indicated.

The definitive treatment of the diseased cervical stump presents an entirely different problem. We do not adhere to the older concept that management of the diseased cervical stump does not differ from treatment of the diseased cervix when the uterus has not been removed. If routine examination reveals an asymptomatic, normal cervical stump then the patient should be warned of its existence and cautioned to have periodic examinations. If there is first or second degree asymptomatic prolapse of the cervical stump only careful observation is indicated. If third degree prolapse is present, regardless of symptoms, the cervix should be removed and the vaginal vault resupported. Regardless of the degree of prolapse, however if prolapse is causing pelvic pain or bearing down sensations (which may be reproduced by pulling on the cervix with a tenaculum) then it is necessary to extirpate the organ as well as repair the prolapse. These general rules for prolapse of the stump are applicable even to elderly or debilitated patients. The operative procedure is a simple one with no shock. The peritoneal cavity is not necessarily opened and early ambulation with few or no complications is the rule.

TeLinde believes it safer to remove a cervical stump transabdominally. He states that as a result of pentonealization of the cervical stump at the time of supravaginal hysterectomy the bladder is intimately bound to it and consequently the 'blind dissection' from below endangers the bladder resulting in a large percentage of vesicovaginal fistulas. Our experience does not substantiate his views, for there were no fistulas in our entire series although the stump was removed by the vaginal route in 121 cases and by the transabdominal route in only 2 cases.

Simple erosion and superficial infection of the retained cervical stump may be cauterized with the actual cautery in the office and the

patient should return in 6 weeks for sounding of the canal to preclude the possibility of the development of a stricture.

The results of cauterization in cases with long standing chronic infections with considerable hypertrophy endocervicitis, nabothian cysts, and parametritis have been generally poor. Once the infection has reached this stage and is responsible for the pelvic pain, the backache, dyspareunia, leucorrhoea and the urinary discomfort, the only certain method of cure is the complete removal of the cervical stump.

Strictures of the cervical canal in our series probably could have been prevented by removal of the entire uterus at the time of operation rather than by reliance on the supra vaginal route and cauterization of the cervix. Others might have been prevented by proper follow up examination after cauterization, or by realization that the diseased process in the cervical stump was too far advanced to respond to cauterization. If the stricture has already developed but there are no symptoms, repeated office dilatations are of little benefit. The only corrective measure, therefore is surgical excision. Of course, once empyema of the stump has developed, removal is mandatory.

Polyps of the cervical stump should all be removed and studied microscopically. If the polyps are causing no symptoms and are not superimposed on a chronic infection removal of the polyp with cauterization of the base may be the only treatment necessary. However if the polyps are causing such symptoms as contact bleeding and leucorrhoea and are superimposed on a chronic inflammatory process severe enough to cause symptoms, then surgical extirpation is indicated.

It has already been stated that biopsy should be performed on any cervical stump from which there is bleeding and then the stump should be removed *in toto* except in cases of advanced carcinoma of the stump. It is believed that excision is mandatory in spite of the fact that results of previous biopsies may have been reported as merely chronic infection.

Carcinoma of the cervical stump should be treated by the application of radium or roent

gen ray or by excision depending upon the type and the clinical stage. The management of carcinoma of the cervical stump will not be discussed here but it is mentioned because 7 cases were encountered in this series. The reader is referred to the bibliography for the many excellent articles on this subject (1, 2, 4, 9, 15).

Endometriosis of the retained cervix is usually secondary to pelvic endometriosis either being maintained by persistent ovarian function or by replacement hormone therapy. If asymptomatic, careful observation is advocated. If symptomatic, as were all the cases in our series, surgical removal coupled with roentgen therapy administered for the express purpose of causing cessation of function of remaining ovarian tissue is indicated. Estrogenic replacement therapy if being given should of course be discontinued.

Fibroids of the cervical stump even though symptomless should be extirpated with the cervix. All in this series caused symptoms. Whenever they occur it is believed that the patient is materially benefited by their removal.

Other authors in discussing the treatment of various pathologic conditions of the retained cervix, advocate repeated deep cauterization, conization and amputation. In our series 22 patients had been subjected to such procedures without alleviation of symptoms. It must be stressed then that the only method of relieving symptoms and curing the entire pathologic process if hypertrophy and hyperplasia are present, is complete extirpation of the stump.

RESULTS

There were no deaths or complications in this series of cases (Table IV). It is believed that the technique recommended entails no hazard to the bladder or ureter. Of the 123 patients 100 were completely relieved of symptoms. In 11 of the 14 remaining cases there were no follow up examinations. Since 8 of these 11 patients failed to return for follow up examinations it may be assumed that they were not completely relieved. The 3 others were operated upon too recently for follow up examination. There were 3 other patients in

TABLE IV — RESULTS

	No. cases	Percent
Mortality	0	0.0
Morbidity	0	0.0
Completely relieved	100	88.6
No follow-up examination	11	8.9
No relief	3	2.4
Total	123	

this series who were either not relieved or only partially relieved. One was relieved of all difficulties except urinary frequency and dysuria which also failed to respond to urologic treatment. One patient who experienced no relief was found on follow up examination to have a cystic mass in the right adnexa, about 8 centimeters in diameter. This case was probably diagnosed incorrectly. The third failure was a patient, complaining of pelvic pain, dyspareunia, leucorrhea, dysuria and frequency who had had previous supravaginal hysterectomy, appendectomy and cholecystectomy for the same symptoms. It was believed that all her symptoms were arising from an infected cervical stump. The cervix was removed vaginally and at the same time an incisional hernia was repaired and bilateral salpingo-oophorectomy was performed. She was examined many times postoperatively but she continued to have the same complaints for which no urologic or gynecologic cause could be found. Examination of this patient by Dr. Curtis Tyrone (13) who removed the cervical stump revealed that a portion of the cervical stump remained. He states that at the time of removal he merely amputated the cervical stump, brought the cardinal ligaments together at the midline, and sutured the vaginal mucous membrane over this structure similar to a Spalding-Richardson procedure. At the latest operation performed less than a week ago he found an old abscess behind the vaginal vault involving the portion of the cervical stump which was remaining. This patient is now completely relieved of symptoms.

SUMMARY

1. Methods of diagnosis of symptoms which arise from a diseased cervix have been described.

2. The performance of total hysterectomy in all indicated cases is urged.

3. The symptomatology pathology and treatment of 123 patients in whom the cervical stump was removed are discussed.

4. The importance of recognizing the cervical stump as the origin of many patients complaints is emphasized.

INGUINAL AND FEMORAL HERNIOPLASTY

CHESTER B McVAY M.D., Ph.D., F.A.C.S. Yankton South Dakota, and
BARRY J ANSON A.M., Ph.D (Med Sci.) Chicago, Illinois

IN the years between 1938 and 1943 the authors reported upon studies concerned with the anatomy of the inguinal and femoral regions.¹ Certain inaccuracies in the conventional accounts of these regions were pointed out and detailed features were described and figured. It became apparent early that some of the older misconceptions accounted for the confusion that exists concerning the repair of inguinal and femoral hernias, and that some of the principles laid down for their operative correction found meager basis in anatomic structure.

Since completion of the morphological study the senior author has applied the resulting principles to the repair of inguinal and femoral hernias. In the current article the authors will record steps in the operation now rather widely employed² and will present a series of one hundred cases of groin hernia operated upon by the method to be described.

MATERIAL AND METHODS

The surgical material upon which the authors' account is based consists of 100 consecutive operations for indirect inguinal direct inguinal or femoral hernias and anatomic studies made during the past 14 years. The illustrations were prepared from dissections upon male cadavers, the successive surgical steps duplicating those followed in actual hernioplasty.

Admittedly, the surgical series is small a fact which calls for some explanation regarding the type of hernias repaired and the time interval represented in the follow up. It is

the conviction of the authors and others (Bartlett 1946) that the small indirect inguinal hernia, which constitutes the majority of groin hernias, should have no recurrence rate if properly evaluated at the time of operation and that therefore it is the large indirect the direct inguinal and the femoral hernias that constitute the problem in hernia repair. Although the two procedures will be described in detail it is essential in examination of the tabulated statistics to recognize that the abdominal ring repair (illustrated in Fig. 2) is used only in the small indirect inguinal hernia and that the procedure for all the others being the same is called reconstruction of the inguinal wall (illustrated in Figs. 3, 4 and 5).

The series of 100 cases is divided into two parts: 35 patients operated upon at the University Hospital Ann Arbor Michigan between the years 1939 and 1943 (Table II) and 65 patients operated upon at Yankton South Dakota, in the 18 months between January 1, 1946 and July 1, 1947 (Table III). In the interval between 1943 and 1946 the senior author served with the 298th General Hospital and although many hernias were repaired during that period by the method hereinafter described no record of surgical result was kept.

Reference to the tabulations (in which the hernias are separated into groups) will reveal that in the first group the interval since operation is 5 to 8 years but the follow up is incomplete and in the second group the elapsed time is too short (10 to 28 months) to state definitely that there will be no recurrence. However it is worthy of note that of the 100 cases 56 of the hernias can be classified as difficult to repair (of which 12 were recurrent) and that to date there has been no known recurrence.

Comparison of the two groups of cases will illustrate the difference in the type of hernia

encountered in a large charity institution as compared with the incidence of the various types encountered in private practice. In general, it can be stated that patients with the more difficult hernias tend to enter the large institutions, and that about twice as many recurrent hernias are seen in such hospitals as in private practice. The reversal of the ratio between those requiring simple repair of the abdominal ring and those requiring a reconstruction of the inguinal wall is apparent in the two series of cases.

GENERAL CONSIDERATIONS

A Anatomy It seems unnecessary here to describe the detailed anatomy of this region since the authors have done so in earlier articles. However there are certain fundamental anatomic facts that must be clearly understood if the rationale of the authors procedure is to be understood. The inguinal ligament plays no role in either operation; no sutures are placed in it; it is freed by blunt dissection to demonstrate more clearly the underlying femoral sheath and open the way to

the superior pubic (Cooper's) ligament. It is not generally appreciated that the inguinal ligament is a free margin and that, inferior to this aponeurotic edge the fasciae that invest either surface of the external oblique aponeurosis are continued into the thigh as the fascia lata (McVay and Anson, 1940). When the inguinal ligament is freed and retracted inferiorly (caudally) as described later under technique it is simply shelled out of this fascial bed.

The posterior inguinal wall is a composite layer consisting of the most caudal portion of the transversus abdominis aponeurosis and its investing fasciae (Figs. 1a and 1b) the fascia on the inner or peritoneal surface is the transversalis fascia (Fig. 1b). Whereas the transversalis fascia is easily separated from the transversus muscle laterally (Fig. 1b) in the medial area where the muscle becomes aponeurotic, the fascia and the aponeurotic fibers are for all practical purposes fused. The strength of the posterior inguinal wall is directly proportional to the number of aponeurotic fibers it contains. Caudal to the point where aponeurotic fibers of the transversus contribute to the rectus sheath, the insertion is into the superior pubic (Cooper's) ligament; this insertion continues laterally to the medial margin of the femoral ring (Fig. 1b). Although aponeurotic fibers terminate at this point, the transversalis fascia is earned inferi-

Fig. 1. a, The inguino-femoral region, anterior view. Dissections of a cadaver in which the skin and subcutaneous fascia have been completely removed. The external oblique aponeurosis has been opened in the direction of its fibers, beginning at the subcutaneous inguinal ring and extending superolaterally. The incision duplicates that used in the repair of inguinal hernia. The inguinal ligament, freed from its fascial bed, has been retracted inferiorly to demonstrate the femoral sheath (as in all of the following hernial repairs). The superior flap of external oblique aponeurosis is pulled superomedially to demonstrate the underlying rectus sheath. The latter is incised, for relaxation of the layer in the "reconstruction" of the inguinal wall. Next beneath the delicate cremaster fascia has been cut (at ††) near the junction of the internal oblique with the cremaster muscle. The cord has been drawn inferiorly

to expose the posterior inguinal wall, the transversus abdominis aponeurosis and fascia (at †). Defects in this layer constitute the problem in the three major types of groin hernia. b, The same specimen, the inguinal wall from within. Peritoneum and preperitoneal connective tissue have been removed. The line bracketed for the superior pubic ligament records the normal length of the insertion of the transversus abdominis aponeurosis into the ligament. Neither the inguinal nor the lacunar ligaments are visible at this stage of the dissection, although they are invariably pictured in textbooks which illustrate this posterior view. Actually the transversus conceals these ligaments. The point at † is similarly marked in Fig. 1a for orientation. It is approximately central in the area of Ifesselbach's triangle, with whose wall the problem of hernioplasty is chiefly concerned.

only through the vascular lacuna as the anterior layer of the femoral sheath (Figs. 1a and 1b). Medially, at the lateral border of the

rectus muscle the transversus aponeurosis passes anterior to the rectus muscle, thus contributing its substance to the rectus sheath.

(below the linea semicircularis) the transverse fascia on the contrary divides to invest the rectus muscle thus forming the rectus fascia. The internal oblique muscle as a rule lies superior to the area with which the present account is concerned. The latter is not a factor in groin hernias hence it does not enter into the repair unless it is aponeurotic—and then it is included in the sutures.

The important feature in the anatomy of the inguinofemoral region as it pertains to the three types of groin hernia is their dependence (small indirect variety excepted) upon a defect in the same layer. This layer is the transversus abdominis aponeurosis and its investing fasciae in the area of Hesselbach's triangle. This area may conveniently be referred to as the posterior inguinal wall (Figs. 1a and 1b). A direct inguinal hernia presses forward directly through this aponeuroticofascial layer (Fig. 4a). A large indirect inguinal hernia encroaches upon it from the lateral side (Fig. 3a) in those cases in which the medial wall of the neck of the indirect hernia lies against the rectus muscle; the posterior wall is completely destroyed forming in an attenuated state part of the covering of the base of the hernial sac. In a femoral hernia the femoral ring is enlarged medially at the expense of the insertion of the posterior wall into the superior pubic ligament (Fig. 5a) and is thus a narrowing of the insertion of this layer. Whether the etiology of a femoral hernia is in part due to a congenitally narrow insertion of the posterior wall into the superior pubic ligament the authors are not prepared to say. However it is important to record that in a series of cadavers variation in the breadth of this insertion was observed with corresponding variation in the width of the femoral ring. In cases of femoral hernia the femoral ring is invariably enlarged medially at the expense of this insertion and the medial wall of the ring lies against the lacunar ligament. This circumstance accounts for the misleading statement that the medial wall of the femoral ring is the lacunar ligament.

B. Surgery. In the second group (Table III) comprising 65 cases the patients were ambulated on the first postoperative day, skin sutures removed on the fifth and the patients

discharged on the fifth to seventh postoperative day. Patients with abdominal ring repair were allowed unlimited activity 2 weeks after operation; those requiring complete reconstruction of the inguinal wall were allowed light duties in 2 weeks, and unlimited activity 1 month after operation. The distinction between light and heavy work has been made, because most members of this group of patients are farmers whose regular duties would call for heavy lifting and riding such vibrating machines as tractors, combines, and mowing machines.

Advanced age was not regarded as a contraindication to the repair if the patient's general physical condition was good and his symptoms were incapacitating. Five members of this group were in the sixties, 3 in the seventies, and 1 was 82; all of them were actively farming and the hernia in each case had proved to be incapacitating. Of the 4 patients over 70 years of age all had experienced episodes of incarceration; none could wear a truss satisfactorily. There was 1 death in the total number of cases (100) in a man 56 years of age; he succumbed on the seventh postoperative day from a pulmonary embolism (as established by autopsy). Death occurred as he was preparing to leave the hospital; he had been ambulatory much of the time since the first postoperative day.

No primary wound infections occurred. However 2 cases of abdominal ring repair later developed sinus tracts which necessitated the removal of a medium silk mattress suture¹ employed for closure of the abdominal inguinal ring. In each instance, the cause was a technical error: too large a loop of silk had been used. In the group that had undergone complete reconstruction of the inguinal wall there was no instance of wound infection or of extrusion of silk—thus, despite the fact that the suturing (with medium silk) was more extensive than in the cases requiring mere closure of the abdominal inguinal ring.

The skin incision employed is transverse. It serves equally well for the repair of the three types of groin hernia and incidentally it

¹The term "medium silk" as used in this paper refers to No. 30 braided black silk. The term fine silk refers to No. 0000 braided black. B.

Fig 2 a. The inguinal region posterior view. A case of small indirect inguinal hernia. Peritoneum, preperitoneal connective tissue and the hernial sac have been removed to show that in such instances the inguinal region is normal except for slight dilatation of the abdominal inguinal ring. The diameter of the femoral ring is normal as is, likewise, the extent of the pubic ligamentous insertion of the transversus abdominis aponeurosis. b. The inguinal region anterior view. Depicting repair of a small indirect inguinal hernia. The hernial sac has been ligated, excised and retracted out of view. Two sutures have been placed. The first brings together the transversalis fascia and the anterior layer of the femoral sheath. Thereby the slightly dilated abdominal inguinal ring is reduced to normal size. The second suture transfixes the fasciae of the cord to the transversalis fascia, thus preventing subsequent protrusion of lobules of preperitoneal fat. The main area of the posterior inguinal wall being normal, remains undisturbed. The cord has been drawn lateralward to demonstrate the continuity of the transversalis fascia with the anterior layer of the femoral sheath. c. Concluding the surgical steps, the two sutures have been tied and the abdominal inguinal ring closed. The spermatic cord has been returned to a position again; the posterior wall the external oblique aponeurosis will be closed over it.

gives a much superior cosmetic result.¹ The classical incision begins at the pubic tubercle and passes superolaterally, dividing the angle between the inguinal ligament and the linea semilunaris; it cuts across the skin lines (of Langer) and usually leaves a poor scar. The present authors prefer an incision made almost transversely from the level of the abdominal inguinal ring to within 1 centimeter of the midline. The abdominal ring is projected on the skin surface by taking a point half way between the pubic tubercle and the anterior superior iliac spine. The inclination of the in-

cision medially varies slightly from the obese to the asthenic patient, yet follows the lines of Langer.

The subjacent aponeurosis of the external oblique is next divided in the direction of its fibers from the position of the subcutaneous inguinal ring in a superolateral direction to a point 2 or 3 centimeters above the abdominal inguinal ring. The superomedial flap is then developed to its point of fusion medially with the underlying internal oblique aponeurosis. The inferolateral flap is next developed to the inguinal ligament, which is then freed from its fascial bed.

The spermatic cord and the investing cremaster muscle are carefully elevated from the

¹The senior author began using the transverse incision for her hernioplasty in 1911 after observing it used by Dr. F. A. C. Dier. More recently it has been described by Chamberlain.

inguinal canal by incising the delicate cremaster fascia at the junction of the cremaster and internal oblique muscles (Fig. 1a) This is done for each of the three types of groin hernia. Extreme care must be exercised in order to avoid damage to the underlying posterior inguinal wall, which consists of the transversus abdominis aponeurosis and its investing fasciae (Figs. 1a and 1b)

At this point in the operative procedure the surgeon should make the initial evaluation of the posterior inguinal wall noting the strength of the aponeuroticofascial transversus layer and examining for intrinsic defects. Then examination for the presence of an indirect inguinal hernia must be made. Should such be found its distorting and attenuating effect is to be evaluated. If the hernia is direct the weakened and thinned portion is to be excised. Subsequent steps in the operation will be described later. If a femoral hernia has occurred the layer is to be incised just above its insertion into the superior pubic (Cooper's) ligament for maximum conservation of the layer. Even though the hernia is obviously femoral or direct inguinal the structures of the spermatic cord should be separated down through the abdominal inguinal ring in a careful search for even a very small indirect sac. Scrutiny is important, since without question some of the recurrences, in the presence of an indirect sac (intimately associated with the cord and surrounded by the fasciae of the cord) are due to failure to detect such a congenital indirect sac at the time of the first operation.

When the hernia is of the indirect type following completion of the initial inspection of the posterior wall the sac should be partially separated from the funicular structures and fascia, and opened. The index finger is then introduced into the sac, next through the neck at the abdominal inguinal ring. The strength of the posterior inguinal wall is determined by a combination of palpation from the peritoneal side and inspection anteriorly the size of the abdominal inguinal ring is simultaneously noted. In the course of the examination the femoral ring is palpated to rule out a femoral hernia. If repair of the abdominal ring is all that is necessary the sac is completely freed

ligated high and excised. If reconstruction of the inguinal wall is indicated then the complete dissection of the sac awaits the resection of the attenuated portion of the posterior inguinal wall the greater exposure makes high ligation of the sac easier.

Unfortunately no hard and fast rule can be laid down as to just what strength and appearance of posterior wall indicate need for reconstruction and which do not. Neither can it be stated didactically just how large the abdominal inguinal ring should be to justify the reconstruction operation. Both of these decisions must depend upon the judgment of the surgeon. It is worthy of note, however, that this posterior inguinal wall (the transversus abdominis aponeurosis and fused fasciae) is never as strong as certain other aponeurotic layers, such as the rectus sheath. The wall can be thin to the point of translucency and yet be adequate. Many elderly patients operated upon for a small indirect inguinal hernia have not developed a direct inguinal hernia—despite their advanced age. In a general way it can be stated that if the abdominal ring is dilated to more than 2 centimeters in diameter there is sufficient encroachment into the area of direct inguinal hernia (Hesselbach's triangle) to necessitate the reconstruction of the entire posterior inguinal wall.

SURGICAL TECHNIQUE

A. Abdominal ring repair. This procedure is followed in caring for the small indirect inguinal hernia (Figs. 2a to 2c). They represent the majority of groin hernias. The use of the word small does not refer to the length of the sac but to the diameter of the abdominal inguinal ring.

After opening the sac and making sure that no femoral hernia or direct inguinal hernia exists, the surgeon dissects the sac free of all cord fasciae and related structures proximal ward through the abdominal ring. Ligation is done with a chromic catgut pursestring suture, and the sac is excised (Fig. 2b). After ligation and excision of the sac, the ligated neck should retract at least 2 centimeters above the fascial abdominal ring if it does not the fact indicates that dissection has not been

Fig 3 a, The inguinal region posterior view. Simulating a case of large indirect inguinal hernia. Peritoneum, preperitoneal connective tissue and the hernial sac have been removed to demonstrate the aponeuroticofascial defect. The abdominal inguinal ring is greatly dilated, and the inferior epigastric vessels displaced medialward to the edge of the rectus abdominis muscle. More than half of the posterior inguinal wall has been compromised by the dilatation of the abdominal inguinal ring yet there is no direct inguinal herniation and the femoral ring is normal in size. b, The same specimen anterior view. The spermatic cord is enlarged, owing to the contained large indirect hernial sac and to hypertrophy of the fascial investments of the cord. The inguinal ligament has been pulled inferiorly to expose the underlying femoral sheath. The superior flap of the external oblique aponeurosis has been drawn medialward to demonstrate the manner in which it fuses with the internal oblique aponeurosis to form the rectus sheath. The relaxing incision is made just lateral to this line of fusion (dotted line at 1). A second incision is made between the strong portion of the posterior wall, and the area attenuated by the enlarged abdominal ring (dotted line at 2). c, Continuing the procedure, the incisions (represented by the numbered lines in Fig 3b) have been

made, and the thinned portion of the posterior wall has been excised completely. The femoral sheath and superior pubic ligament are exposed. The investments of the spermatic cord have been trimmed to normal size by excising the now redundant fascial coverings. The new strong, lower margin of the transversus abdominis aponeurosis (posterior wall) will be sutured to the superior pubic ligament, in the area from the pubic tubercle to the femoral vein, and from this latter point the transversalis fascia will be sutured to the anterior wall of the femoral sheath (dotted line indicating the line of suture). d, Concluding the procedure, the strong posterior wall has been sutured to the superior pubic ligament (at 1) and the anterior layer of the femoral sheath (at 3, along the dotted line illustrated in Fig 3c). The spermatic cord (at 4) has been drawn farther lateralward to show the line of suture as it extends upward to and closes, the abdominal inguinal ring. The relaxing incision (at 2) is now an open triangular defect protected behind by the lower end of the rectus muscle and its tendon of pubic origin. The lateral margin, retracted and angular is usually sutured to the underlying tendon of the rectus abdominis. This step completes the repair. The spermatic cord is replaced against the posterior wall and the external oblique aponeurosis is closed over it.

high enough. Dissection of the hernial sac is carried out with a scalpel and should extend in the bloodless field of loose areolar tissue immediately adjacent to the peritoneum of the sac.

Thus far the description is a restatement of the fundamental problem presented by this type of hernia and one recognized since the

time of Bassini. In addition to the peritoneal processus vaginalis the surgeon will frequently encounter pedunculated protrusions of the preperitoneal layer of fascia and fat among the structures of the cord. They vary in number from one to several they should be dissected free up through the abdominal ring ligated and excised. Ligation is important

since they contain a vascular stalk. They should be removed for two reasons first because a small abdominal inguinal ring cannot be made while such protrusions remain within it second because they are likely to act as an entering wedge for recurrent herniation through the abdominal inguinal ring (consonant with Cloquet's concept regarding the role of lipoma in epigastric hernia)

Following ligation and excision of the sac, the fascial margins of the abdominal ring are identified. The cord is pushed lateralward and the abdominal inguinal ring is snugly closed medial to the spermatic cord by one or two medium silk mattress sutures these approximate the transversalis fascia to the subjacent anterior layer of the femoral sheath (Fig. 2b suture 1). That these are merely portions of the same layer can be demonstrated at the medial margin of the ring. An additional fine silk suture is placed within the ring in the manner of a pursestring which serves to gather the fascia of the cord at several points, approximating it to the transversalis fascia above (Fig. 2b suture 2). The last suture serves to close completely the abdominal inguinal ring and to prevent subsequent protrusion of lobules of preperitoneal fat through the ring.

The abdominal ring is considered closed if the tip of the little finger can be inserted through the ring along with the cord structures. With the use of such closure there have been no cases of postoperative edema of the testis or of subsequent atrophy of the testis. The remainder of the procedure consists simply in dropping the cord back into normal position and closing the external oblique aponeurosis over it with the use of interrupted fine silk sutures. The subcutaneous inguinal ring is made just small enough to prevent an examining finger from passing through it. It is important to note that not a single suture is passed through or into the posterior inguinal wall. In this type of hernia the authors consider anything other than abdominal ring repair not only unnecessary but inadvisable. Initial appraisal (with a palpating finger through the neck of the hernial sac) having indicated that the wall is sufficiently strong to contraindicate reconstruction (hereinafter)

and that no femoral hernia is present, suturing in the standard kind of repair would only expose the patient to the possibility of a direct recurrence through a suture hole or a tear. While performing some other lower abdominal operation an indirect inguinal hernia may be repaired after the method of Jennings¹ however this approach seems unnecessarily complicated for repair of a small indirect inguinal hernia.

B Reconstruction of the posterior inguinal wall

1 Large indirect inguinal hernia.—When the abdominal inguinal ring is dilated to exceed a diameter of 2 centimeters and is encroaching upon the posterior inguinal wall is narrowing Hesselbach's triangle (Figs. 3a and 3b) the entire posterior wall should be reconstructed. The first step in the procedure is dissection of the sac. Duplicating the procedure employed in the operation for the small indirect variety exploration is made through the sac then after a high ligation the sac is excised. If a direct hernia or a femoral hernia exist together or if the three are present, they are to be converted into one sac by the so called Houget maneuver. Two incisions are then made through the posterior wall (Fig. 3b at 1 and 2). The first incision is made in the rectus sheath just lateral to the point of fusion of the external oblique aponeurosis to the sheath and extends from pubic crest superiorly for a distance of 3 or 4 centimeters (Figs. 3b and 3c). This is the relaxing incision² which allows the sheath to slide laterally and inferiorly when the repair is completed. It further permits suture to the superior pubic ligament without tension. The remaining defect is protected by the rectus abdominis muscle and its tendon of origin. The second incision begins at the abdominal inguinal ring and extends medially and inferiorly to the superior pubic ligament. In completion of the latter incision all attenuated fascia and aponeurotic fibers from the posterior inguinal wall are excised (Figs. 3b and 3c). Redundant portions of the fascia of the spermatic cord and of the cremaster muscle hypertrophied

Jennings, Anson, and Wright (1933)

²Atlas, 928, Kuesoff, 940; McEay and Anson, 943; Tenet

Fig. 4. a, The inguinal region, posterior view. Simulating a case of direct inguinal hernia of pedunculated type. Peritoneum, retroperitoneal connective tissue, and the hernial sac have been removed to demonstrate the aponeuroticofascial defect. The defect affects the inguinal wall in direct course. The abdominal inguinal ring is normal in size and the inferior epigastric vessels are not displaced (in contrast see Fig. 3a). The femoral ring is normal in caliber and position and the insertion of the transversus layer into the superior pubic ligament is normal in breadth. b, The same specimen, anterior view. Showing the bulge in the inguinal wall. The spermatic cord contains no processus vaginalis. It is retracted inferiorly and laterally to demonstrate the size of the hernial sac. As in the procedures hereinbefore described and figured, the inguinal ligament is retracted inferiorly to demonstrate the femoral sheath. The first incision (at dotted line 1) is the relaxing incision in the rectus sheath, made just lateral to the line of fission of the external oblique and internal oblique aponeuroses. The second incision (at dotted line 2) follows the upper margin of the attenuated posterior wall, and is the superior boundary of that portion which is to be excised. c, Continuing the procedure, the relaxing incision (at 1) has

been made, and through its slightly retracted borders the underlying rectus muscle can be seen. The succeeding incision (at 2) has also been made. Additionally all of the attenuated portion of the inguinal wall has been excised to expose the superior pubic ligament and the margin of the femoral sheath. The excision of aponeurotic fibers and fascia extends to the abdominal inguinal ring. The hernial sac has been removed, the spermatic cord retracted farther lateralward. The posterior inguinal wall along its newly made margin will be sutured to the superior pubic ligament and to the femoral sheath (along dotted lines). d, Concluding the surgical steps, the strong superior and medial portion of the transversus layer has now been drawn downward and sutured to the superior pubic ligament (at 2) and to the anterior femoral sheath (at 3). The spermatic cord has been pulled even farther lateralward (at 4) to demonstrate that the suture line extends far enough laterally to close snugly the abdominal inguinal ring. The defect produced at the relaxing incision (at 1) by the sliding inferolateralward of the transversus layer is again demonstrated (compare Fig. 3d). As before, the spermatic cord is replaced against the newly made posterior wall and the external oblique aponeurosis is closed over it.

through the presence of the large contained hernia are likewise excised (compare Figs. 3b and 3c). The inguinal ligament is freed by blunt dissection and retracted inferiorly to expose the femoral sheath and the fascia of the pectineus muscle (Fig. 3c). Shreds of attenuated transversus layer (posterior inguinal wall)

are trimmed from the superior pubic ligament; the preperitoneal connective tissue and fat are pushed inward to expose the superior pubic ligament throughout its length; similarly the femoral vein and the margin of the anterior layer of the femoral sheath are exposed—and especially that part of the sheath where the

retched fascia was excised. The troublesome preperitoneal fat and areolar tissue may be kept out of the field merely by pressure with small gauze pack, held with a small ribbon tractor which is to be introduced from the lateral side.

Sutures are then placed for the closure, beginning medially at the pubic tubercle and extending as far lateralward as the femoral vein. Each suture should include the transversus abdominis and fused transversalis fascia above and the superior pubic ligament below. They are to be placed about 2 millimeters apart. These sutures are not tied until two additional sutures are placed. After the last suture is placed in the superior pubic ligament close to the femoral vein the next suture includes the same layer above but below it passes deeply into the pectineus fascia (where the leader from the label *Annulus femoralis* touches the femoral ring in Fig. 3c). The next suture includes transversalis fascia superiorly, which point the layer is usually muscular below it includes the anterior layer of the femoral sheath at the latter's medial extremity. Returning to the first suture placed near the pubic tubercle the operator ties them in the order in which they were placed. At this point the pack and the retractor are removed from the preperitoneal space, and the remainder of the closure is accomplished by approximating the transversalis fascia to the anterior layer of the femoral sheath far enough lateralward to make a snug abdominal inguinal ring (Fig. 3d). The new abdominal inguinal ring is usually 1 to 1.5 centimeters lateral to the normal position of the ring over the femoral vein. Thus the new ring is either directly over the femoral artery or slightly lateral thereto (Fig. 3d). The relaxing incision has converted an original slit into a triangular defect (compare Figs. 3b, 3c, and 3d). If the underlying rectus abdominis is indurated, the retracted lateral margin of the defect may profitably be sutured to it with interrupted fine silk sutures (Fig. 3d) however if it is fleshy suturing is either omitted or the lateral retracted edge is sutured to overlying external oblique aponeurosis.

The presence of the artificial defect need occasion no uneasiness. If its lateral margin is

lifted and exploration carried a few millimeters farther lateralward the transversalis fascia will be found to invest the rectus muscle as the rectus fascia (McVay and Anson 1940). This layer effectively prevents the preperitoneal layer from protruding through the defect in the rectus sheath. Thus the strong remaining portion of the posterior inguinal wall and part of the rectus sheath are moved laterally and inferiorly to a new position and are sutured without tension to form a new posterior wall that becomes the supportive equivalent of the normal parietes. Since no additional reparative measures are necessary, the cord is dropped back into normal position and the external oblique aponeurosis is closed over it to produce a snug subcutaneous inguinal ring. This maneuver restores the normal obliquity of the inguinal canal and also fills up a trihedral space made by the repair. This potential dead space exists because the new posterior wall does not possess redundancy inferiorly equal to that of the normal undisturbed, inguinal wall. Ambulation and intra abdominal pressure should early produce the normal redundancy.

2 The direct inguinal hernia.—In this type of hernia the defect is one of direct course through the abdominal wall (Fig. 4a). Although it may be associated with one or the other or with both of the two other types of groin hernia only the direct variety need be considered. The fundamental problem remains unaltered by the concurrent presence of the other parietal defects.

All surgeons are familiar with the different types of direct inguinal hernia, from the pedunculated variety that may strangulate to those exhibiting expansive bulging of the entire wall in which the neck of the sac is as broad as any other portion. It is often difficult to decide whether the wall is merely relaxed (as it frequently is in asthenic individuals) or whether a direct hernia exists. While it is not the province of this paper to consider this problem it would not be amiss to say that if the bulge is symptomless, it is wise not to intervene—especially if the patient is in the old-age group.

Exposure elevation of the spermatic cord and examination of the cord for the presence

Fig. 5 a, The inguofemoral region, posterior view simulating a case of femoral hernia. As in the preceding steps of dissections, serous and subserous layers and the hernial sac have been removed to demonstrate the defect in the aponeuroticofascial portion of the transversus. The defect is an enlarged femoral ring. The dilated ring encroaches upon the inguinal wall from the inferolateral aspect, with resultant decrease in the breadth of insertion of the transversus layer into the superior pubic ligament. There is no defect directly through the lower abdominal wall, such as occurs in direct inguinal hernia. Furthermore, the abdominal inguinal ring is not dilated as it is in cases of indirect inguinal hernia. b, The same specimen seen from anterior view. The spermatic cord, retracted inferolaterally contains no processus vaginalis. The bulge is seemingly inguinal in position; this appearance is the result of displacement, downward, of the inguinal ligament to expose the hernia in the femoral canal. Just medial to the bulge in the femoral canal the recess (shaded) represents the more posterior course of descent of the normal inguinal wall to the lateral part of the superior pubic ligament. The relaxing incision (dotted line at *x*) and the incision in the posterior wall (dotted line at *y*) are, generally, the same as those employed in the previously described conditions. The second incision permits access to the real defect, namely, a femoral ring dilated through narrowing of the insertion of the transversus layer into the superior pubic ligament. However, in this instance, the second incision (at *y*) is close to the ligament for maximum preservation of the intact transversus layer (posterior inguinal wall). c, Con-

tinuing the steps in the technique the relaxing incision (at *r*) has been made (as in Figs. 3c and 4c). The second incision (at *s*) has been completed, to expose the superior pubic ligament and the margin of the femoral sheath. The hernia sac has been excised, the enlarged femoral ring exposed. The suture-line (dotted in figure) along the superior pubic ligament, extends to the femoral vein and will obliterate the femoral ring. A similar method is employed in the repair of direct inguinal and large indirect inguinal hernia (Figs. 4c and 3c, respectively). Whereas in the two preceding types of hernia, the first part of the suturing at the femoral sheath follows the margin of the femoral ring, in the present instance the first suture is made into the pectineus fascia lateral to the dilated medial margin of the femoral ring. The defect to be repaired is smaller than in the two preceding instances (compare Figs. 3c and 4c). d. Concluding the reparative steps, the procedure duplicates that in either of the two preceding instances (Figs. 3d and 4d). Sutures (at *t*) bring the lateral retracted margin of the relaxing incision into contact with the underlying rectus tendon. Other sutures (at *u*) bring the transversus layer downward to the superior pubic ligament. The final sutures (at *v*) fasten the transversus layer to the anterior layer of the femoral sheath. The last suture (shown by retracting the spermatic cord) extends into and closes the abdominal inguinal ring. The repair of the femoral hernia having been accomplished, the spermatic cord is dropped against the posterior wall, back into the normal position, and the external oblique aponeurosis is closed over it.

of an associated indirect sac are carried out in the manner previously described. In the penduculated direct inguinal hernia with a small rigid neck the hernia may pass not only through the subcutaneous inguinal ring but may even become scrotal—contrary to the usual statement that a direct inguinal hernia never descends to scrotal level. The incisions are made in this type of hernia exactly as in the preceding instance (Figs. 4b and 4c). Usually the second incision is more superiorly placed than in the large indirect variety since more of the posterior inguinal wall is attenuated in a direct hernia of the diffuse type (Fig. 4b). All of the thinned aponeurotic-fascial layers are excised; the superior pubic ligament and the anterior layer of the femoral sheath are identified (Fig. 4c). The second incision extends upward into the abdominal inguinal ring. The base of the cord is again examined for an indirect hernial sac.

Further handling of the direct hernial sac depends upon its size and character. All penduculated sacs are opened and examined for incarcerated or adherent viscera. The neck is closed in the usual manner and the sac excised. This type of sac if reduced without being opened and excised can result in an internal type of hernia without visible or palpable external evidence. The small diffuse type of sac need not be opened but all large diffuse sacs should be. Excess peritoneum is cut away and the serous wall then closed in a linear fashion—repair thus being easier because there is less tissue to be depressed out of the operative field.

Repair is then carried out by steps exactly duplicating those outlined under the repair of the large indirect hernia. The transversus layer is approximated to the superior pubic ligament and the anterior layer of the femoral sheath (Fig. 4d); the cord is restored to normal position and the external oblique aponeurosis closed over it. An additional note is pertinent concerning the defect in the rectus sheath resulting from the relaxing incision (Fig. 4d). Although the defect is usually larger than in the preceding instance no case was encountered in which the direct hernia was too large to be repaired by this method or in which aponeuroticofascial transplants were required.

3. The femoral hernia.—In this type of hernia, whether congenital or acquired, the defect is associated with a narrowing of the insertion of the transversus layer into the superior pubic ligament (compare insertion Fig. 2a with narrowed insertion Fig. 5a). The exposure, the elevation of the spermatic cord and careful examination of the cord for possible occurrence of an indirect sac are carried out as previously outlined in the discussion of large indirect inguinal hernia. If the inguinal ligament is freed and retracted inferiorly much of the hernial bulge is exposed above the inguinal ligament (Fig. 5b). The incision in the transversus layer is made as close to the superior pubic ligament as possible (Figs. 5b and 5c). In the authors' experience strong posterior inguinal walls were found in cases of femoral hernia, a circumstance which permits the low incision. Over the femoral vessels the incision is made just below the termination of the transversus muscle where the transversalis fascia becomes the anterior portion of the femoral sheath.¹ This incision is carried lateralward into the abdominal inguinal ring (Fig. 5c). Again the base of the cord is examined for a small indirect sac. The femoral sac is pulled into the position of a direct inguinal hernial sac (Fig. 5b) with cutting of the inguinal ligament if necessary. Then the sac is opened and after exploration of content it is ligated and excised. The repair then follows the plan set forth in the descriptions of the two preceding types (note similarity in Figs. 3c, 4c, and 5c and 3d, 4d and 5d). The relaxing incision is employed (Figs. 5c and 5d). Usually the defect produced over the rectus muscle is

¹The femoral rim is easily exposed. It should be seen in every case to avoid errand error. The needle. Certain smaller vessels, however, can cause the surgeon considerable difficulty. I encase of the superior pubic ligament, small artery and vein are usually encountered, running medially along the ligamentous root, the transversalis. If troublesome they should be doubly ligated and cut. The possible occurrence of anomalous obturator vessels should also be kept in mind. Veins in the peritoneal fat are easily injured; occasionally they are cancerous, especially in the area adjacent to the bladder. The freeing of the femoral sheath the following vessels are encountered immediately beneath the fascia: the origins of the inferior epigastric, the deep iliac circumflex and the external spermatic vessels. In the majority of cases, the external spermatic vessels do not pass through the abdominal inguinal ring but gain access to the fasciae of the cord through separate apertures just medial to the abdominal inguinal ring. If the latter vessel hinder the making of tight closure of the abdominal inguinal ring, they should be ligated and cut.

smaller since the only compromise in the posterior wall is the redundancy produced by the slight overlapping at the suture line along the superior pubic ligament and the anterior layer of the femoral sheath. The spermatic cord is dropped back into normal position and the external oblique aponeurosis closed over it.

SUMMARY

A single operative procedure is presented for the repair of large indirect inguinal direct inguinal and femoral hernias. This operation consists essentially of restoring inguino-femoral anatomy to normal status. Repair is similar because the three types of hernias represent defects in the same layer at different points.

Since there is no anatomic defect in the inguino-femoral region in the uncomplicated small indirect inguinal hernia other than the presence of a congenital hernial sac and a slight dilatation of the abdominal inguinal ring it is recommended that this type of hernia be repaired by removal of the sac by accepted methods and by subsequent tightening of the abdominal inguinal ring.

EFFECTIVENESS OF DICUMAROL PROPHYLAXIS AGAINST THROMBOEMBOLIC COMPLICATIONS FOLLOWING MAJOR SURGERY

A Four Year Survey 3 304 Cases

WALTER D WISE, M.D., F.A.C.S F FORD LOKER, M.D., and
CHARLES E. BRAMBEL, Ph.D. Baltimore, Maryland

THE underlying causes of thrombosis and embolism and their prevention have in recent years received much consideration. Two opposing schools of thought have arisen: (1) those who advocate chemotherapeutic measures with anti-coagulants (3, 4, 8, 9, 20, 24, 25) prophylactically and therapeutically employed; and (2) those who advocate surgical intervention, i.e., venous ligation (1, 2, 17) prophylactically and therapeutically. The reports of the effectiveness of early ambulation are still contradictory. A recent investigation (39) reveals that the incidence of thrombosis postoperatively is not appreciably affected, but the mortality rate from pulmonary embolism was reduced to one half.

The approach that has shown the greatest promise has been chemotherapy with the anti-coagulants dicumarol and heparin. Intensive studies with favorable results are appearing in increasing volume from various clinics in this country (3) and abroad, e.g., Scandinavia (9, 50).

It was our purpose to investigate on a long term basis whether it is possible to find any reduction in the frequency of thromboembolic disease with an accompanying decrease in the number of fatal pulmonary embolisms. Chemoprophylaxis with dicumarol together with other measures as indicated were used in a routine program in unselected cases of major abdominal and pelvic procedures. Surgery has reached the stage where, in many types, particularly in elective surgery, we are work-

ing for an improvement in mortality in fractions of 1 per cent. The prophylactic therapy must not create additional hazards to the patient, otherwise it defeats its purpose.

Dicumarol has been used in our work because it can be administered by mouth, has been found by us to be easier to regulate than heparin, and it is far less expensive. When a rapid alteration of the blood clotting mechanism is desired, it is necessary to use heparin by means of which an immediate effect may be obtained. But this anticoagulant is too expensive for routine application, and economics play an important role in any clinical project.

The incidence of venous thrombosis, diagnosed clinically in postoperative cases, ranges between 1 and 10 per cent (5, 21). The actual incidence of postoperative thrombosis is not known, nor is the frequency of pulmonary embolism known. Data about fatal embolism are more certain. Pulmonary embolism is the cause of about 5 per cent of all postoperative deaths when all the figures throughout the country are considered. The incidence rate or death rate is probably lower now than it was some years ago, due to a better understanding of the pathology and treatment, but our data do not show a significant difference. It is now so low that some investigators, namely Lam and Hooker, question whether all the effort that would have to be made to reduce the mortality by the use of anticoagulants, with their added dangers, justifies their use.

Some surgeons are advocating and practicing ligation (17) of part of the venous return system from the lower extremities, therapeutically and as a prophylactic. It seems to be justifiable to attempt to find some less radical procedure than ligation of the femoral vein.

From the Department of Surgery and the Department of Clinical Biochemistry, Mercy Hospital and the University of Maryland School of Medicine, Baltimore, Maryland. This investigation was made possible through grant in aid by the Abbott Laboratories, North Chicago, Illinois.

the external iliac vein, or vena cava. There are many reasons for trying to find a medical rather than a surgical prophylactic. Some advocates of prophylactic ligation are now recommending ligation of both femorals in all patients who are to undergo major surgical procedures or to be bed confined for any length of time or who are over 50 years of age. When one thinks of the number of operations that are done on individuals of this age, and that this number will be increasing with the increased longevity and greater security in surgery it makes a rather appalling picture to think that each of these may have to have two additional operations. Furthermore, ligation of the femorals does not always block the vein above the source of danger, as in pelvic and abdominal surgery the embolus may originate in the pelvic vessels or in the deep femoral when the superficial femoral was ligated. Furthermore, such ligations are not without their morbidity and mortality.

McCartney has shown that at autopsy of 4,070 postoperative deaths, 11.5 per cent manifested thromboembolism, and for 5.3 per cent pulmonary embolism was thought to be the cause of death. An effort is being made to show that the possibility of thromboembolism is present in 10 or more per cent of patients with an increase of 25 to 50 per cent in adults and older patients operated upon or bed confined. These findings emphasize the importance of some type of prophylaxis which must follow one or all three conditions conducive to thrombotic complications: i.e. (1) slowing of the blood stream, (2) endothelial damage, and (3) enhanced coagulability of blood (21). Too little has been said about the excessive use of sedatives and narcotics preoperatively and postoperatively producing long hours of quiet, which diminishes respiratory excursion and probably in other ways slows the circulation.

Numerous procedures (21) have been proposed to offset factors resulting in thromboembolism. Many of these measures have supposedly been shown by statistical studies, of ten of doubtful significance, to lower the incidence of thrombosis and embolism.

Another phase of this subject, which does not seem to have been sufficiently stressed is

the occurrence of serious disabilities in many patients who do not have pulmonary embolism, but whose pathology is limited to one or both lower extremities. We all see too many patients suffering with swollen, partially disabled legs which, if not cared for, lead to more serious trouble, such as ulceration and no matter how well cared for cause much disability.

Reference has been made to the occurrence of thromboembolism in patients confined to bed for a long period but it has not been sufficiently emphasized that it is not by any means limited to surgical patients. Many cases are seen on the medical service (16, 28, 31). The efficacious use of dicumarol in coronary thrombosis for the prevention of thromboembolism a frequent complication in this clinical category, has now been confirmed (32, 36, 37, 49).

As already stated, if the figures quoted above are anywhere nearly true, it seems justifiable to try to find some procedure much less radical than vein ligation and more suitable for common usage. The anticoagulants specifically dicumarol appear to offer a satisfactory approach if expertly used and meticulous care is exercised. *However one must bear in mind that the use of an "induced controlled hemorrhagic state" to combat a transitory physiological clotting tendency is potentially hazardous by its very nature.*

An important phase of chemoprophylaxis is that it inhibits further thrombosis throughout the body (3, 12) while venous ligation is local in its sphere of influence.

CLINICAL MATERIAL

The routine prophylaxis program at Mercy Hospital in actual practice includes all types of surgery but for purposes of presentation and discussion the category where greatest predisposition to thromboembolic complication appears namely major pelvic and abdominal surgery or combinations has been selected. The major operations included in this investigation are as follows: (1) all types of hernioplasty and combinations, cholecystectomy with and without exploration of the common duct, (2) hysterectomy and gynecological abdominopelvic surgery, (3) appendectomy for varying degrees of severity of appen-

EFFECTIVENESS OF DICUMAROL PROPHYLAXIS AGAINST THROMBOEMBOLIC COMPLICATIONS FOLLOWING MAJOR SURGERY

A Four Year Survey 3 304 Cases

WALTER D WISE, M.D. F.A.C.S. F FORD LOKER, M.D., and
CHARLES E. BRAMBEL, Ph.D., Baltimore Maryland

THE underlying causes of thrombosis and embolism and their prevention have in recent years received much consideration. Two opposing schools of thought have arisen. (1) those who advocate chemotherapeutic measures with anti coagulants (3 4 8 9 20 24 25) prophylactically and therapeutically employed and (2) those who advocate surgical intervention i.e. venous ligation (1 2 17) prophylactically and therapeutically. The reports of the effectiveness of early ambulation are still contradictory. A recent investigation (39) reveals that the incidence of thrombosis postoperatively is not appreciably affected, but the mortality rate from pulmonary embolism was reduced to one half.

The approach that has shown the greatest promise has been chemotherapy with the anti coagulants, dicumarol and heparin. Intensive studies with favorable results are appearing in increasing volume from various clinics in this country (3) and abroad e.g. Scandinavia (9 50).

It was our purpose to investigate on a long term basis whether it is possible to find any reduction in the frequency of thromboembolic disease with an accompanying decrease in the number of fatal pulmonary embolisms. Chemoprophylaxis with dicumarol together with other measures as indicated were used in a routine program in unselected cases of major abdominal and pelvic procedures. Surgery has reached the stage where in many types, particularly in elective surgery we are work-

ing for an improvement in mortality in fractions of 1 per cent. The prophylactic therapy must not create additional hazards to the patient otherwise it defeats its purpose.

Dicumarol has been used in our work because it can be administered by mouth has been found by us to be easier to regulate than heparin and it is far less expensive. When a rapid alteration of the blood clotting mechanism is desired, it is necessary to use heparin by means of which an immediate effect may be obtained. But this anticoagulant is too expensive for routine application and economics play an important role in any clinical project.

The incidence of venous thrombosis, diagnosed clinically in postoperative cases, ranges between 1 and 10 per cent (5 21). The actual incidence of postoperative thrombosis is not known nor is the frequency of pulmonary embolism known. Data about fatal embolism are more certain. Pulmonary embolism is the cause of about 5 per cent of all postoperative deaths when all the figures throughout the country are considered. The incidence rate or death rate is probably lower now than it was some years ago due to a better understanding of the pathology and treatment, but our data do not show a significant difference. It is now so low that some investigators, namely Lam and Hooker question whether all the effort that would have to be made to reduce the mortality by the use of anticoagulants, with their added dangers justifies their use.

Some surgeons are advocating and practicing ligation (17) of part of the venous return system from the lower extremities therapeutically and as a prophylactic. It seems to be justifiable to attempt to find some less radical procedure than ligation of the femoral vein

From the Department of Surgery and the Department of Clinical Biochemistry, Mercy Hospital and the University of Maryland School of Medicine, Baltimore, Maryland. This investigation was made possible through grant in aid by the Abbott Laboratories, North Chicago, Illinois.

the external iliac vein or vena cava. There are many reasons for trying to find a medical rather than a surgical prophylactic. Some advocates of prophylactic ligation are now recommending ligation of both femorals in all patients who are to undergo major surgical procedures or to be bed confined for any length of time or who are over 50 years of age. When one thinks of the number of operations that are done on individuals of this age, and that this number will be increasing with the increased longevity and greater security in surgery, it makes a rather appalling picture to think that each of these may have to have two additional operations. Furthermore, ligation of the femorals does not always block the vein above the source of danger as in pelvic and abdominal surgery the embolus may originate in the pelvic vessels or in the deep femoral when the superficial femoral was ligated. Furthermore, such ligations are not without their morbidity and mortality.

McCartney has shown that at autopsy of 4 070 postoperative deaths, 11.5 per cent manifested thromboembolism and for 5.3 per cent pulmonary embolism was thought to be the cause of death. An effort is being made to show that the possibility of thromboembolism is present in 10 or more per cent of patients with an increase of 25 to 50 per cent in adults and older patients operated upon or bed confined. These findings emphasize the importance of some type of prophylaxis which must follow one or all three conditions conducive to thrombotic complications i.e. (1) slowing of the blood stream, (2) endothelial damage, and (3) enhanced coagulability of blood (21). Too little has been said about the excessive use of sedatives and narcotics, preoperatively and postoperatively producing long hours of quiet, which diminishes respiratory excursion and probably in other ways slows the circulation.

Numerous procedures (21) have been proposed to offset factors resulting in thromboembolism. Many of these measures have supposedly been shown by statistical studies, of ten of doubtful significance, to lower the incidence of thrombosis and embolism.

Another phase of this subject, which does not seem to have been sufficiently stressed, is

the occurrence of serious disabilities in many patients who do not have pulmonary embolism, but whose pathology is limited to one or both lower extremities. We all see too many patients suffering with swollen, partially disabled legs which, if not cared for, lead to more serious trouble such as ulceration, and no matter how well cared for cause much disability.

Reference has been made to the occurrence of thromboembolism in patients confined to bed for a long period, but it has not been sufficiently emphasized that it is not by any means limited to surgical patients. Many cases are seen on the medical service (16, 28, 31). The efficacious use of dicumarol in coronary thrombosis for the prevention of thromboembolism a frequent complication in this clinical category, has now been confirmed (32, 36, 37, 49).

As already stated, if the figures quoted above are anywhere nearly true it seems justifiable to try to find some procedure much less radical than vein ligation and more suitable for common usage. The anticoagulants, specifically dicumarol appear to offer a satisfactory approach if expertly used and meticulous care is exercised. *However one must bear in mind that the use of an induced controlled hemorrhagic state to combat a transitory physiological clotting tendency is potentially hazardous by its very nature.*

An important phase of chemoprophylaxis is that it inhibits further thrombosis throughout the body (3, 12) while venous ligation is local in its sphere of influence.

dicus (4) various types of genitourinary tract surgery (5) colonic and abdominoperineal resections. Thoracic procedures, radical mastectomies and operations on extremities for recent and old fractures, although receiving the anticoagulants for prophylaxis, were not included because of insufficient numbers in these categories compared to those selected. The clinical diagnosis of thrombosis and embolism was established by the classical symptoms and signs. Patients with transitory signs have been included. Suspected cases of pulmonary embolism accompanied by sudden pain in the chest followed by fever of several days duration were examined by roentgenography. Postmortem examination of a number of cases confirmed the clinical findings.

The numbers for the period 1944-1947 appear themselves sufficient for comparison and formulation of at least tentative conclusions (Table I). This survey also includes data for 6 preceding years (1938-1943) during which anticoagulants were not used. Previous investigations have shown that large numbers of patients are required in statistical studies of methods of prophylaxis. Also it is necessary to eliminate cyclic variations in incidence. It must be quickly said however that perhaps

some may think larger numbers are desirable as well as a longer period of years of study before any definite conclusion can be drawn.

Postoperative cases were selected for dicumarolization where there was no obvious hazard of hemorrhage. The vast majority are consecutive. The patients not treated were those on the private services of the visiting staff who were not favorably disposed toward a routine prophylactic anticoagulation program. These patients made up the control or untreated group. Also a small group of patients were not treated prophylactically for the following reasons. The clotting mechanism of the blood was already shifted in favor of bleeding as shown by routine prothrombin clotting time determinations which were above normal throughout hospitalization. It was our impression that these patients were not subject to thromboembolic complications, and none were encountered in this group. They were excluded from the untreated and treated series. The general age range was from the second decade to the eighth. Patients younger than 20 years of age have been excluded in this survey. The numbers of untreated and treated patients by years are presented in Table I.

METHODS

Dicumarol (23) has been administered orally to 3,304 patients in the prophylactic program reviewed in this paper. The initial dosage of the drug was 200 milligrams administered on the second postoperative day. Subsequent doses were given on alternate days to maintain a relative prothrombin activity level of not under 40 per cent of normal. Dicumarolization was continued throughout the hospitalization period and discontinued when the patient was discharged. The average total consumption was 600 to 800 milligrams.

The generally accepted contraindications to the use of dicumarol (3) are (1) the presence of definite renal insufficiency (2) the presence of definite hepatic insufficiency or hepatogenous jaundice particularly if associated with decrease in prothrombin activity (3) subacute bacterial endocarditis (4) purpura of any type (5) blood dyscrasia with tendency to bleed and (6) recent operation on the brain or spinal cord. Dicumarol should be given cautiously (3) to patients who have (1) ulcerative lesions open wounds or potentially bleeding surfaces (2) vomiting due to gastric or intestinal drainage or (3) dietary or nutritional deficiency. If an operation is contemplated ample time should elapse for the return of prothrombin activity to near normal if dicumarol is administered before the operation. If an emergency surgical procedure is necessary on the patient who has decreased prothrombin activity owing to dicumarol large doses of synthetic vitamin K derivative (72 milligrams hylknone) should be given intravenously to combat the reduced activity of blood clotting components before the operation is begun (11, 45).

For success of the prophylactic program with the anticoagulant dicumarol it is essential to have a centralized control of the drug and a laboratory which insures execution of a unified pattern—a specialized team to carry on anticoagulant therapy by means of rigidly standardized procedures. Such a pattern is conducive to efficiency and fixing of responsibility. The Mayo Clinic is an example of this type of discipline (6, 18).

In the administration and control of the anticoagulant dicumarol a sensitive repro-

ducible and standardized procedure for the estimation of an induced decrease in prothrombin activity is positively essential to insure uniformity and comparability of laboratory data. During the course of this investigation we have expended much effort to establish such a procedure (6). Barker (18) of the Mayo Clinic has likewise emphasized this precaution if reproducible and predictable response to dicumarol is to be obtained. A modified single stage prothrombin clotting time procedure developed by us has been used routinely. It is most unfortunate that the prothrombin clotting time techniques in different parts of the country are not uniformly standardized since much confusion exists with regard to interpolability of accumulated data. Efforts are being directed to establish a standard procedure by a national committee¹ and conference².

The anticoagulant effect of dicumarol can be detected only by a prolongation of the prothrombin clotting time of plasma (23). In our laboratory a modification of the original Quick method (40) was developed which shows a higher degree of sensitivity to variations in prothrombin activity and dependable reproducibility. Such reproducibility must be possible with normal plasma and plasmas during varying degrees of the dicumarol effect. The only means of standardization has been saline dilution of normal plasma to approximate the prothrombin clotting time values obtained during the administration of dicumarol. Standardization of this procedure has been beset with almost unsurmountable technical difficulties. A number of other described procedures (26, 35, 38, 44) have been tried but were not very satisfactory. The two stage method (47) was not adaptable for large numbers of daily routine determinations.

As previously reported (7, 46) the prothrombin clotting time of saline diluted plasma could be used to determine a tendency toward hyper-coagulability of plasma (7, 13, 33, 44, 48). Two prothrombin clotting time determinations have been made routinely on

¹ American Heart Association Committee on the Use of Anticoagulants in the Treatment of Coronary Thromboses with Myocardial Infarction. Irving S. Wright, chairman.

² Josiah Macy Jr. Foundation Conference on Blood Clotting and Allied Problems, January 1948.

all patients, namely on undiluted plasma and saline diluted plasma (12.5%). This procedure has proved very satisfactory as demonstrated by the results presented in this paper.

It was decided that the prothrombin clotting time of saline diluted plasma (12.5%) on the second postoperative day would determine whether or not prophylaxis was indicated. If this value was 70 seconds or lower the patient was given dicumarol prophylactically. With very few exceptions (less than 0.05 per cent of all treated cases) this plan was satisfactory. To wait longer than the second day to see if the prothrombin time of diluted plasma will start to rise is to invite thrombotic complications. The prothrombin clotting time of diluted plasma taken preoperatively or on the day of operation is unreliable because of the unpredictable physiological increase in activity of the blood clotting elements after the trauma of operation.

The clinical results herein reported have been obtained with conservative dicumarolization that is, decreasing the prothrombin activity to about 40 per cent of normal and maintaining it during the hospitalization period. Other workers (3) notably the Mayo Clinic and Scandinavian investigators (9, 50) recommended that plasma prothrombin activity be maintained at 10 per cent or 20 per cent of normal. Further study and accumulation of evidence will reveal which level is more efficacious. Drastic or radical dicumarolization does not completely eliminate thromboembolic complications (Scandinavian work and Mayo Clinic—3, 9, 50) but does increase the risk of bleeding and incidence of hemorrhagic complications. Fatalities have been reported ascribable to dicumarol effects (10, 14, 42).

Fibrinogen determinations were made in a large number of cases in the present series to ascertain if liver toxicity to dicumarol could be demonstrated. The methods developed by Morrison were used. Analyses were made on alternate days during the hospitalization period.

RESULTS

A survey of Mercy Hospital clinical records for the period 1938 through 1947 is tabulated according to years with respect to number of

cases, total thromboembolic complications, embolic phenomena and deaths (Table I). It is possible to compare the distribution of such complications for a period of 6 years, without anticoagulants prophylactically used with a 4 year period during which the routine anticoagulant program was in operation. In this period in about 61 per cent of the major abdominopelvic surgical cases patients received dicumarol prophylactically. The vascular complications consisted of the classical types, namely thrombosis of the leg or pelvic veins, and pulmonary infarction with single or multiple embolic manifestations.

For the 4 year period (1944-1947) under investigation, there was a total of 5,334 major abdominopelvic operations. There were 2,030 patients untreated with 21 thromboembolic complications (1%) 8 embolic complications (0.4 of 1%) and 5 deaths from pulmonary embolism (0.2 of 1%). In summary there were 34 of the 2,030 untreated patients with vascular complications (1.6%).

There were 3,304 patients treated prophylactically with dicumarol with 4 thromboembolic complications (0.1 of 1%) as compared to 1% of the untreated) pulmonary infarction (0.03 of 1% as compared to 0.4 of 1% of the untreated) and 1 death (0.03 as compared to 0.2 of 1% of the untreated) probably not actually due to pulmonary embolism. In summary there were 6 of the 3,304 treated patients with vascular complications (0.18 of 1% as compared to 1.6% of the untreated).

A comparison with the years 1938-1943 reveals that in this period there were 7,220 untreated patients with 57 thromboembolic complications (0.8 of 1% as compared to 1% for 1944-1947) 20 embolic phenomena (0.3 of 1% as compared to 0.4 of 1% for 1944-1947) and 8 deaths from pulmonary embolism (0.1 of 1% as compared to 0.2 of 1% for 1944-1947) (Table I). In summary for 1938-1943 of the 7,220 untreated patients there were 85 patients with vascular complications (1% as compared to 1.6% for 1944-1947).

For the 10 year period 1938-1947 of 13,554 patients, 9,250 were untreated and 3,304 treated. There were 78 of the untreated (0.8 of 1%) with thromboembolic complications. There were 28 of the untreated (0.3 of 1%)

TABLE II.—CRITICAL RATIOS (C.R.) OF THE DIFFERENCE BETWEEN THE PERCENTAGES OF TREATED AND UNTREATED PATIENTS SHOWING COMPLICATIONS

Complications	1944-1947			1938-1947			U treated		
	Untreated N=2,030	Treated N=3,304	C.R.	Untreated N=2,030	Treated N=3,304	C.R.	1938-1943 N=730	1944-1947 N=330	C.R.
Thromboembolic	0.0344	0.0181	3.9	0.0343	0.008	6.4	0.07804	1.344	0.09
Embolic	0.0320	0.00308	2.6	0.0307	0.000308	4.8	0.03770	0.003040	77
Embolic deaths	0.02463	0.000308	9	0.01405	0.00030	2.2	0.00008	0.000463	.8
Total	0.0748	0.0085	4.8	0.1864	0.0085	8.8	.77	0.0748	.6

with embolic complications and 1 of the treated (0.03 of 1%) with embolic complications. There were 13 deaths from pulmonary embolism among the untreated (0.03 of 1%) and 1 death (probably not due to pulmonary embolism) (0.03 of 1%) among the treated. In summary there were 119 cases of vascular complications among the 9250 untreated (1.2%) and 6 cases of vascular complications among the 3304 treated (0.18 of 1%).

The critical ratios derived from a statistical analysis (prepared by the Reverend Henry Burke S.S. of Saint Mary's Seminary) indicate certain of the differences between the percentages to be significant (Table II). Statistically it can be shown that with a critical ratio of 2.58 the odds are 100 to 1 against an obtained difference being due to chance or random errors in sampling. But the critical ratios of 3.9, 4.2, 4.8, 6.4, and 8.2 indicate beyond a reasonable doubt the superiority of treatment to nontreatment with dicumarol as employed by us for the reduction of postoperative vascular complications. By our data it is also statistically shown to be probable but not certain that dicumarol therapy as used during the course of this investigation is superior to nontreatment in reducing deaths from postoperative pulmonary embolism. There is no evidence that untreated patients during the period 1944-1947 fared any better in avoiding postoperative vascular complications than similar patients did between the years 1938-1943.

The data obtained may also serve as a basic reference in establishing a preprophylactic treatment incidence of vascular disorders on the combined surgical services at Mercy Hospital. A comparison is made between a period of 4 years when dicumarol was not used with

a 4 year span at which time the prophylactic program was in operation.

Patients receiving dicumarol totalling 3304 compared with 2030 not getting such therapy during the same period by comparison reveal a significant reduction in vascular complications.

A review of the surgical procedures in our prophylaxis series where the expectancy rate is fairly well established and is the highest reveals the following. There were 325 cases of hysterectomy with 2 instances of mild venous thrombosis and no embolic manifestations. These cases might be considered failures of conservative anticoagulation. There were 423 cases of hernioplasty with no thromboembolic complications. In the untreated group the expected incidence of thrombosis and embolism was encountered in this category. A number of untreated patients manifested no clinical signs of peripheral occlusion but suddenly terminated fatally from embolism.

Dicumarol has been administered to over 5500 miscellaneous patients (confined and ambulatory) in periods varying from 10 days to 3 years. Of the 3304 patients in the prophylactic program reviewed in this paper the incidence of major bleeding requiring blood transfusions is less than 0.1 of 1 per cent (Table III), and minor bleeding controllable with massive intravenous dosage of synthetic vitamin K derivative (hydroquinone) is about 2 per cent. The explanation for this low percentage of bleeding hazard may possibly be found in the

TABLE III.—HEMORRHAGIC INCIDENCE FOLLOWING DICUMAROLIZATION

Number of cases major abdominal pelvic surgery	3304
Requiring blood transfusion	1
Minor bleeding	76
Deaths due to dicumarol	0

fact that conservative anticoagulation therapy was used and hyperreaction to the drug was readily detected. Bleeding has not been a cause of great concern.

Other side reactions such as gross hematuria, nausea, vomiting and diarrhea occurred to the extent of about 3 per cent. Minor purpuric manifestations were found in less than 1 per cent of the cases studied. Bleeding at the surgical site was noted in a few cases. In general, minimal untoward side reactions were encountered. No deaths ascribable to excessive dicumarol effect were encountered in the series of cases presented in this paper.

Fibrinogen concentration varied in postoperative patients according to the expected pattern and independently of the degree of dicumarolization. There was no evidence of liver toxicity (19) due to the drug in so far as this blood constituent was concerned. This finding is another argument in favor of conservative therapeutic use of the anticoagulant.

DISCUSSION

Granting the multiplicity of factors contributing to thromboembolic disease following major surgery, anticoagulation has offered what appears to be a satisfactory approach for decreasing the incidence of such complications. The choice of anticoagulant is governed by the facility and safety with which it can be used. In principle, an induced controlled hemorrhagic state (decreased coagulability of blood) to forestall a potential tendency to thrombosis has been employed. A delicate balance between bleeding and clotting has to be maintained. The findings herein reported indicate that conservative inhibition of the components of the blood coagulation system has yielded encouraging results.

However, it must be borne in mind that there are factors other than increased clotting tendency which may give rise to thromboembolism. It is not to be construed that controlled alteration of blood clotting components is entirely responsible for the results obtained. But it is of interest that a reduction in the incidence of thromboembolism is possible when this factor is considered particularly in the light of results obtained with other procedures, i.e., early ambulation and venous ligation.

The availability of these procedures makes possible a judicious selection of one, or appropriate combinations of them. It does seem that enhanced coagulability of the blood, or the ability to propagate existing clots is the primary factor. Checking this tendency chemotherapeutically satisfactorily forestalls the undesired effects whether there be a sluggish circulation or a pre-existing focus in the form of a small clot. Anticoagulation on this basis seems to be a more rational approach and appears to be substantiated by practical application.

To maintain a balance of the blood clotting components on the hemorrhagic side without deleterious effect on the patient requires delicate methods and a disciplined team. It is deplorable that coagulability of blood can be expressed only in crude relative terms rather than specific quantitative ones. The chemistry of the blood coagulation components and their mechanism is still in a chaotic and controversial state although definite progress (30, 34, 41) is being made steadily. In this direction, therefore, during the course of this investigation, laboratory control procedures including reagents had to be developed while lacking in desired precision yielded information which made anticoagulation reasonably safe in our hands. A competently disciplined team served as an indispensable adjunct. Also, our knowledge of the mechanism of action of the anticoagulants available, i.e., dicumarol and heparin, is meager and incomplete. The use of this procedure is fraught with a number of apparently insurmountable difficulties—a veritable primeval wilderness that needs to be carefully and systematically explored.

The clinical use of dicumarol is not without bleeding hazards (3, 9, 10). The most accepted thesis of the mechanism of dicumarol effect (21) is the inhibition of prothrombin production by the liver since it has been found that prothrombin activity decreases following oral administration of this drug. It is generally assumed that hemorrhagic manifestations—purpura and bleeding from surgical site—are directly correlated with the degree of depression of prothrombin activity. Experience reveals that in some instances these manifestations appear at levels of prothrombin activity

ity where they would not be expected. Unfortunately the number of such occurrences is small. Therefore even conservative depression of prothrombin activity may show some minor bleeding manifestations. It falls out of the category of hyperreaction and possibly may be classified as sensitivity or idiosyncrasy of the coagulation system but associated with capillary weakness. Our election of a conservative pattern has resulted in an incidence of hemorrhage that is negligible. Such a procedure has the added advantages that such prothrombin activity levels are more readily maintained and it avoids the prolonged cumulative effect of the drug. Some clinics maintain that a drastic reduction in prothrombin activity is necessary to insure prophylaxis and that protection against thromboembolic complications is directly related to the degree of reduction in prothrombin activity. Due to the inadequacy of present methods and lack of standardization it is impossible to make a comparison of the effects of prothrombin depression carried at various levels in different clinics. It is also difficult if not impossible to compare prothrombin activity levels reported from various laboratories because of the heterogeneity of prothrombin estimation procedures in use.

To make the giving of dicumarol effective but above all to insure safety it must be realized that there is required a laboratory setup of specialized type with specifically trained and skilled technical workers. Moreover it is impossible to cause therapeutic depressions of a patient's prothrombin activity by dicumarol at a consistent level and without danger of hemorrhage unless prothrombin testing is done with a thromboplastic reagent which is adequately sensitive and which will constantly and consistently give reproducible values in a series of saline dilution of normal plasma. The effort necessary to surmount these difficulties raises the question of the advisability to pursue such a course of prophylaxis to reduce an already relatively small incidence of fatal and nonfatal thromboembolic complications.

CONCLUSIONS

1. The foregoing data reveal beyond doubt a statistically significant reduction in the inci-

dence of venous thrombosis following major abdominopelvic surgery when the oral anti-coagulant dicumarol was used prophylactically.

2. The reduction in mortality rate due to fatal embolism is statistically probable.

3. Conservative depression of prothrombin activity to 40 to 50 per cent of normal gave satisfactory prophylaxis and negligible hemorrhagic complications.

4. No evidence of liver toxicity due to dicumarol in the doses given was noted as revealed by fibrinogen determinations.

5. The necessity for rigid standardization of laboratory procedure for gauging the dicumarol effect is unequivocally essential for the success of a prophylaxis program.

SLIDING INGUINAL HERNIA OF THE COLON

The Abnormal Peritoneal Folds and a Simple Safe Method of Restoration

ROSWELL K. BROWN M D., F.A.C.S., Buffalo, New York

A SLIDING hernia may be defined as one in which part of the sac is formed by the serosa of the contained viscus. The colon in a sliding hernia has an adventitious surface which is not covered by any peritoneum either visceral or parietal (Fig 1 lower left) This area is the mesenteric border and adjacent zones which have been denuded by unfolding of the leaves of the mesentery (1 2 3 5 7) The peritoneum of the mesentery is inside-out as hernial sac (6) The blood supply of the bowel is in its normal position along the mesenteric border but it lies in

areolar tissue and is not enclosed in the peritoneal coverings of the mesentery

The diagnosis of the sliding nature of a hernia may be suspected clinically It is not well retained by a truss There is usually relatively little, if any constriction of the hernial mass at the inguinal rings However the exact diagnosis is usually not made prior to operation

The surgical treatment is somewhat dangerous if the surgeon does not understand the true nature of the lesion (a) Inadvertent opening into the bowel may result from dissection to open the sac too far laterally (b) If the operator attempts to treat a sliding or

Fig. 3. Hernia opened and its sliding nature determined.

parapertoneal hernia as he would an old in carcerated hernia with adhesions, by dissecting the bowel free he will encounter the blood

Fig. 4. Repair site palpated from within peritoneal cavity. Bowel held away from the groin behind operator's hand.

Fig. 5.

vessels (c) Attempts to repair the defect through exposure of the inguinal region alone tend to fasten the bowel at the groin. Thus the bowel and its blood supply are doubly endangered first in the dissection and then in the repair.

METHOD OF REPAIR

Repair of the inguinal canal is rendered safe and easy by reduction of the hernia by traction on the bowel from above through a separate opening into the peritoneal cavity (Figs 2 and 3). This can be done through the same skin incision by retracting the upper leaf of the external oblique aponeurosis and separating the internal oblique and transversus muscles in the direction of their fibers as in a McBurney incision (4, 5). Care should be taken to avoid injury to the iliohypogastric and ilioinguinal nerves and their branches by separating the muscles well above them. The hernia is reduced by traction from above and the opening previously made in the sac is now found in the lateral leaf of the mesentery near or at the intestine (Figs. 1 and 3). The bowel and its blood vessels are held away from the groin through the upper incision and a sound reconstruction of the inguinal canal may be accomplished easily and safely. The intra-abdominal aspect of the groin is palpated and inspected through the upper wound during the course of reconstruction of the posterior wall of the inguinal canal (Fig. 4). After repair of the posterior wall of the inguinal canal the rent in the lateral leaf of the mesocolon is closed through the upper incision. This may be done with some infolding of redundant peritoneum. The two leaves of the mesentery may be stitched together at an avascular point which is close to the root of the mesentery in order to prevent future unfolding.

Finally the muscle-splitting incision is closed and the external oblique aponeurosis is closed with appropriate imbrication.

Fig. 5 Closure of the lateral leaf of the mesocolon. The opening was made when this peritoneum formed the fundus of the hernia sac.

SUMMARY

1. A sliding hernia should be suspected when there is a relatively large ring and the mass is not well retained by a truss.

2. Adhesions of bowel to hernia sac should not be confused with sliding hernia. Adhesions may be separated with safety. Dissection along the mesenteric border of the bowel in a sliding hernia is unnecessary and undesirable.

3. A separate opening into the peritoneal cavity enables the surgeon to restore the normal anatomic relationships and renders repair of the groin simple and safe while the bowel is held away from the line of suture.

RESECTION OF THE GREAT VEINS ON THE LATERAL PELVIC WALL

ALEXANDER BRUNSCHWIG M.D. F.A.C.S. and THOMAS S. WALSH M.D.
New York, New York

PREVIOUS experience has shown that ligation of the common iliac, external iliac, or hypogastric veins is feasible and may entail only moderate swelling of the leg when either of the first two of these vessels is occluded. The purpose of this report is to record the experiences obtained when large segments of the external iliac and the hypogastric veins with the terminations of the tributaries of the latter are resected (Fig. 1). Such dissection was found to be necessary in the course of excision of malignant neoplasms primary in the uterus or adnexa which had extended laterally to involve these vessels. A perusal of the literature has not revealed reports of such procedures and of the sequelae incident thereto.

CASE 1. Chr. female 50 years of age. Hysterectomy in 1943 for neoplasm of the cervix, had been

From The Memorial Hospital Center for Cancer and Allied Diseases.

Fig. 1. Diagram of large veins of pelvis showing segments resected (broken line). I.e. lower portion of common iliac vein, most of external iliac vein and hypogastric vein with its branches.

performed in another institution. Irradiation therapy in various forms had been administered to the pelvis at intervals during 1944 to 1947. Pelvic examination revealed recurrent neoplasm involving the fundus of the vagina with firm induration extending to the right pelvic wall. There were no rectovaginal nor vesicovaginal fistulas but the rectal and vesical walls seemed invaded by carcinoma.

On January 24, 1948, complete excision of the bladder, vagina, recurrent carcinoma and pelvic colon, with colostomy and bilateral ureteral implantation into colon above colostomy was carried out. (Details of technique of this operation are described elsewhere.) In mobilizing the neoplastic mass that had extended to the right lateral pelvic wall it was observed that the external iliac vein had become obliterated and converted to a dense fibrous cord. The hypogastric vein and common iliac veins were patent and enlarged due to obliteration of the external iliac. The obliterated external iliac vein, the lower segment of the right common iliac vein and the right hypogastric vein were excised with all the pelvic viscera. Branches to the right hypogastric vein were divided at some distance from it. After operation there was marked swelling of the right leg but this did not seriously interfere with function; some cyanosis and pain were present. On the second postoperative day a right lumbar sympathetic block was carried out with novocain followed by symptomatic relief and disappearance of cyanosis. The block was repeated on a subsequent occasion.

The patient was discharged from the hospital on March 7, 1948, and since has been ambulatory. Swelling of the right leg persists but causes no interference with function (Fig. 2). One year after operation the patient remains well and free from evidence of spreading neoplasm.

CASE 2. SB. female 52 years of age. In 1944, left salpingo-oophorectomy for malignant ovarian tumor was performed in another institution. During the past year patient has had severe pain in the right pelvis radiating to the back. She was admitted to Memorial Hospital in February 1948. Pelvic examination revealed a firm mass "frozen" into the right side of the pelvis. Operation was performed February 1, 1948. A neoplastic mass involving the right ovary and tube was found which had extended to the right pelvic wall and had become adherent to the right external iliac vessels. Separation from the artery was readily carried out despite adherence to

Brunschwig, A. Complete Excision of Pelvic Viscera for Advanced Carcinoma, etc. *Cancer* (1948) 77.

the vein necessitated excision of most of the external iliac and the lower portion of the common iliac was also resected together with the hypogastric vein and its branches. Lymph nodes obviously containing metastases were resected from along the lower portion of the abdominal aorta and common and external iliac arteries as a part of the procedure.

Immediately after operation a lumbar sympathetic block was performed (10 c.c. of 2% novocain in the right second and third lumbar interspaces). There was no swelling of the right leg until the second postoperative day. At this time a second block was carried out. The leg then felt warmer but swelling persisted. On the eighth postoperative day swelling decreased. At no time was there severe pain or impairment of function. Patient was discharged on the 21st day after operation and has since remained ambulatory. The swelling of the right leg, confined principally below the knee, has not caused functional impairment (Fig 3). One year after operation the patient remains well.

CASE 3. Stad. female, 58 years of age. Patient had previously received roentgen therapy in other

institutions for advanced carcinoma of the cervix. She was admitted to Memorial Hospital January 17, 1948, and pelvic examination revealed a large ulcerating neoplastic mass replacing the cervix. There was obvious invasion of the bladder. On February 3, 1948, an abdominoperineal excision of the uterus, vagina, bladder and neoplastic mass was carried out with bilateral ureteral implantations into colon. In excising the pelvic tumor it was necessary to remove the right external iliac vein together with the right hypogastric vein *en masse* with the neoplasm. The procedure was carried out in the presence of peri-aortic lymph node metastases as an attempt at palliation for severe pelvic pain and vaginal hemorrhage.

Following operation there was only slight swelling of the right leg and no pain. Paravertebral blocks were not deemed necessary. On the 13th postoperative day a fecal and urinary fistula developed in the perineal wound. She was discharged to a nursing home for terminal care. Pain had been relieved. She succumbed on March 11, 1948, and necropsy was not secured but there had been only slight swelling and no pain in the right leg.

Fig 2

The right external iliac vein, lower segment of right common iliac vein and right hypogastric veins were excised *en masse* with the tumor. The swelling did not appreciably impair function of the right leg.

Fig. 5 Case 4. Venogram taken 3 weeks after operation showing *S* saphenous vein injected in lower thigh. In the absence of right external iliac and hypogastric veins there is return of blood via *E*, subcutaneous veins; lower anterior, bifurcated, all and across *P*, perineum veins on left side.

CASE 4. L. T. Negro male aged 35 years. Patient had received irradiation therapy for epidermoid carcinoma of the vagina in 1946; the lesion was controlled but continued to spread until April 1948, when pain in right pelvis had become very severe. The pain also radiated downward to the right thigh and leg along the distribution of the sciatic nerve. Furthermore, the patient was not able to walk upright because of the pain but walked with hesitation; the body bent forward and to the right. Pelvic examination revealed a dense frozen mass in the right adnexal region.

Laparotomy was performed April 29, 1948. Extensive carcinoma was found in the pelvis with metastatic nodes in the paraortic regions of the retroperitoneal abdominal spaces. In the right pelvis a spherical mass of neoplastic tissue about 6 cm. in diameter was deeply embedded and closely attached to the external iliac and hypogastric veins. It also appeared to be pressing against the roots of

the right sciatic nerve. The mass was excised together with the external iliac and hypogastric veins (the right hypogastric artery was divided and ligated) in an attempt at palliation to relieve the severe pain. (Pan hysterectomy was also carried out.) Immediate recovery from operation was satisfactory. Paravertebral nerve block (right 1st and 3rd and 4th lumbar) with novocain was carried out on the eve of operation and repeated on each of the next 3 days. Two days after operation there was relatively little swelling of the right leg. The midportion of the right thigh measured 10.5 inches compared with 18 on the left; the right leg 13.5 inches compared with 17.6 on the left. After the patient became ambulatory swelling increased in the right leg but did not impede function (Fig. 4). The severe pain present before operation was relieved but because of advancing disease the patient was sent to an institution for terminal care a month after discharge from Memorial Hospital.

DISCUSSION

In view of the resections of external iliac, lower common iliac, and hypogastric veins, the return circulation from the inferior extremity in these patients must be via the large subcutaneous venous plexuses about the hip and perineum (Fig. 5). Subcutaneous veins of the affected leg did not become more prominent following operation. The experiences recorded above indicate that involvement of the external iliac and hypogastric veins does not afford in itself a contraindication for excision of these growths inasmuch as no distressing sequelae develop from such interruptions of the return circulation in one extremity.

SUMMARY

In 4 patients with advanced pelvic neoplasms, excisions of the latter were carried out *en masse* with lower segment of the right common iliac vein, most of the external iliac vein and the hypogastric vein with its branches. The inferior extremity on the side operated upon became somewhat swollen but was not very painful. Subsequent ambulation was not appreciably delayed or impaired and the swelling subsided. Thus, such venous resections may be unhesitatingly carried out if necessary to excise large pelvic neoplasms.

CARCINOMA OF THE CECUM COMPLICATED BY APPENDICITIS OR PARA-CECAL ABSCESS

CON AMORE V BURT MD F.A.C.S., New York, New York

CARCINOMA of the cecum with acute appendiceal inflammation or paracecal abscess has been reported previously in the literature in only 13 instances. Four more of these cases are added here from the records of the Presbyterian Hospital representing a review of 98 operations for carcinoma of the cecum during the 20 years from 1927 to 1947 inclusive.

Most of the patients with this dual pathology have been operated upon with the diagnosis of acute or chronic appendicitis and in a few instances, with the suspicion of the co-existence of carcinoma of the cecum. Their histories usually have been of short duration and indistinguishable from those of acute appendicitis and their physical signs those of a tender mass in the right lower quadrant.

The preoperative diagnosis between acute or chronic appendicitis with its frequently associated induration of the cecum and that of carcinoma of the cecum with infection or abscess is extremely difficult and usually has not been made. However by careful palpation an experienced surgeon should make the proper diagnosis in most instances if he bears in mind the possibility that the 2 lesions may be present at the same time.

Not infrequently the neoplasm of the cecum although not originating in the appendix has obstructed the lumen of the appendix and with superimposed infection has caused an acute appendiceal reaction and even rupture of the appendix with abscess formation. Occasionally a paracecal abscess will form without an apparent rupture of the appendix or the inflammatory reactions secondary to carcinoma of the cecum will obscure the underlying neoplastic process so that detection of the carcinoma is delayed. In a study of 3,400 cases of acute appendicitis Collins found

obstruction of the lumen of the appendix as the etiological factor in 50 per cent of the cases.

The persistence of a draining sinus, fecal fistula or painful right lower quadrant mass following appendectomy or drainage of an abscess has usually led to the ultimate discovery of the cancerous condition in the cecum.

It is the rule rather than the exception in most of the reported cases that some 4 to 6 months have elapsed between the operation for acute appendicitis or drainage of an infected area and the accurate diagnosis and resection of the advanced cancer of the cecum.

HISTORICAL DATA

The first case of carcinoma of the cecum in association with acute appendiceal pathology was reported by Shears in an excellent paper in 1906 in which a primary resection and ileocolostomy was done. His report did not include an histological examination and the diagnosis depended upon the clinical impression of cancer of the cecum with mesenteric adenopathy. There was a very large thickened distended appendix which sprang directly out of the tumor itself very much like that of Case 1 of the present report. In these intervening 42 years very little has been added to the accurate recognition of the pathology and management of the case described by Shears except in respect to modern post-operative care and the amount of tissue removed which has been extended to include the large bowel up to the midtransverse colon instead of stopping the resection just above the cecum.

A careful search of the literature revealed nothing further on this subject until 1922 when Morton presented an excellent comprehensive paper on the differential diagnosis of malignant disease of the cecum from chronic and subacute appendicitis. He also presented a case illustrating this combination of pathology.

From the Department of Surgery, College of Physicians and Surgeons, and the Surgical Service of Presbyterian Hospital, New York.

Fig. 1 Gross specimen showing the ascending colon, cecum and terminal ileum with the carcinomatous tumor surrounding the base of the inflamed appendix.

serosa (Figs 2 and 3). In the highly cellular areas of the tumor there were one or two mitoses per high power field (Fig 4). A review of 17 lymph nodes showed no metastases.

Diagnosis: Carcinoma papillary type moderately well differentiated of the cecum acute perappendicitis.

The postoperative course was extremely satisfactory and the patient was discharged on the 9th postoperative day with good bowel function. Three years after the resection the patient was perfectly well and working at his usual occupation.

CASE 2 PH 286800 K.M. female aged 48 was admitted to the Presbyterian Hospital complaining of severe back pain beginning 4 days previously and of 3 days of severe generalized abdominal pain. She had been rather constipated up to the previous night when a cathartic was very effective.

Physical examination revealed an acutely ill middle aged white female moaning with generalized abdominal pain. Abdominal examination revealed splinting of the right side with acute tenderness over McBurney's point. There was rebound tenderness in both lower quadrants. No mass was palpated. Rectal examination presented diffuse tenderness more marked on the right. Impression: Acute appendicitis with acute local peritonitis. Preoperative blood count showed white blood cells 22,000 with 88 per cent polymorphonuclear leucocytes.

First operation was performed June 2, 1933 drainage of appendiceal abscess.

About 100 cubic centimeters of cloudy turbid peritoneal fluid escaped when the peritoneum was opened. The cecum could not be delivered. The distal half of the appendix was buried in adhesions between the cecum and a loop of gut thought to be

sigmoid near the brim of the pelvis. It was impossible to see what the outer half of the appendix looked like. As the appendix was followed into these adhesions a cavity containing pus was entered.

Through an intermuscular incision the peritoneum was opened and the abscess cavity entered. After unsuccessfully attempting to remove the appendix the operator inserted 3 cigarette drains respectively into the pelvis, the abscess cavity and the lumbar gutter.

Following operation the temperature continued between 101 and 102 degrees for 12 days after which a low grade temperature continued until discharge on the 47th postoperative day. Pulse had ranged between 90 and 120. A rather marked secondary anemia persisted in spite of several transfusions. The morning after the operation, patient was noted to have a right hemiplegia including the face which had been present to a much less marked degree for a long time before the operation. For 4 weeks after the operation there had been a profuse foul fecal discharge from the wound but in the 5th week it had diminished to almost nothing.

September 22, 1933 patient was readmitted with a hard slightly tender nodule in the incision connecting with a large hard mass in the right lower quadrant thought to be a malignant tumor. She was weak and rather markedly anemic. Her bowels had been constipated and she was obstipated for 2 days about 1 week prior to this admission. Barium enema showed that cecum did not fill completely was not mobile and was less flexible than usual. Findings were consistent with carcinoma of cecum.

A second operation was performed October 4, 1933. At this time biopsy of the mass in the abdominal wall showed adenocarcinoma.

Fig. Low power of one half of the appendix, showing the lumen free, mucosa intact, submucosa normal except for fat replacement, which indicates an old inflammatory process, muscularis normal, subserosa presenting marked hyperemia and leucocytic infiltration.

A third operation was done October 11, 1933 (4 months and 9 days after drainage of abscess para-rectal thought to be appendiceal in origin).

There was a manifest tumor attached to the abdominal wall penetrating the skin. Attached to the mass intra-abdominally were 2 loops of small intestine and 1 of sigmoid which seemed to be involved by the growth. The adjacent mesenteric lymph nodes were enlarged and obviously carcinomatous. There were small masses covering the uterus and also in the broad ligament, probably metastases. The aortic nodes were obviously metastatic.

Because of the marked extension along the lymphatic routes the lesion was considered to be hopelessly inoperable and no attempt was made to remove it or to resect the involved intestinal loops. Part of the growth that was protruding above the abdominal wall was coagulated and a good deal of it was removed with the electrocautery. The wound was closed after lymph node and part of the abdominal wall were obtained for histological examination, which showed adenocarcinoma on microscopic section following carcinoma of the cecum.

Patient was discharged in poor condition on the 23d postoperative day. She gradually deteriorated and died on December 13, 1933, a little more than 6 months after the first operation.

CASE 3. PH 435076. L.M. female aged 43, housewife, was admitted to Presbyterian Hospital after 3 weeks of suffering with a severe knife-like pain in the suprapubic region radiating to the anterior superior

ilium. This pain kept recurring and was attributed to intestinal gas. For the previous 3 or 4 days the pain in the right lower quadrant had been increasing in severity and frequency and was associated with sweating, chills and fever during the night. Appetite was poor but there was no vomiting.

Physical examination revealed an obese female in great distress. In the right lower quadrant was a soft, oval, nontender, slightly movable mass of about 7 by 4 centimeters. There was no distention, redness or fluctuation. There was considerable muscle spasm, but no rebound tenderness.

The urine showed some albumen and red blood cells. A kidney-ureter-bladder plate showed no kidney stones. A cholecystogram revealed poor filling and evidence of gall stones. Impression: acute appendicitis with abscess.

The first operation was performed November 5, 1934, and consisted of an appendectomy.

There was a small abscess at the base of the appendix containing about 5 cubic centimeters of pus. Distal to this the appendix lay embedded in a mass of firm tissue, most of which was thought to be mesentery of the appendix. The mass was about 4 by 3 centimeters and was adherent to loops of small intestine and other structures unrecognized in the pelvis. It arose from a broad base of retroperitoneal tissue.

Through a McBurney incision the mass was exposed and a 2 adjacent abscess cavity was entered. A Weir extension was made to expose the mass which

Fig 3. High power of peripheral portion of wall of the appendix with normal muscularis, leucocytic infiltration and hyperemia of subserosa, fibrin deposits on surface.

Fig 4. High power of glandular type of carcinoma of the cecum.

was adherent to the posterior abdominal wall. It was debated whether to remove the mass or simply to drain the abscess. The mass abscess cavity and appendix were removed. No attempt was made to tie off the stump of the appendix. A double drainage tube was placed into the depth of the wound.

Gross pathology. There was a hard fibrous irregular nodular mass 6 by 3.5 by 3.5 centimeters which on section showed densely organized scar tissue, an abscess cavity 1 by 1.5 centimeters filled with friable material and an appendix which was 1.5 centimeters in diameter having a wall 0.4 centimeter thick. The mucosa seemed absent in many places. No point of perforation from the appendix into the abscess cavity could be located. A loop of small intestine was attached to the cecum.

Microscopic examination. Most of the mucosa was preserved. The lumen of the appendix was filled with polymorphonuclear leucocytes, red cells and fibrin. In the mucosa and submucosa there was a very striking infiltration with lymphocytes. The mucosa was not especially edematous or thickened but the submucosa showed edema and a considerable amount of new fibrous tissue. The inflammation became more acute as the periphery was reached and there was a frank purulent exudate with some necrosis outside the muscular coat. Young granulation tissue was seen here. Diagnosis: chronic appendicitis, peritoneal abscess.

Postoperative course was very satisfactory. The wound sinus drained pus but no stool for 27 days. The wound was not quite healed on discharge on the 30th postoperative day.

Patient was readmitted April 1, 1935, for constantly discharging sinus since operation about 5 months previously. Sinus was never fecal.

A second operation was performed April 2, 1935. Exploration of the sinus of the abdominal wall showed that the sinus led to the cecum. The wall of the cecum was hard friable and red.

The tract was followed down to the cecum without breaking into the general peritoneal cavity. The wall of the cecum was opened in trying to expose the bottom of the sinus. Biopsy tissue from the cecum was taken and the opening was closed. Histological examination showed carcinoma of the cecum.

April 13, 1935, a barium enema showed slow and incomplete filling of the cecum, with a filling defect which constricted the lumen.

A third operation was carried out April 15, 1935 (5½ months after the appendectomy). Partial colectomy with end-to-end ileotransverse colostomy and resection of ileum with end-to-end enterocostostomy and ileostomy were done. A small mass was felt in the cecum. None of the enlarged glands were thought to be metastases. The liver was found to be normal.

A transverse incision was made at the level of the umbilicus. The loop of small intestine attached to the cecum was inadvertently entered and it was then resected with an end-to-end anastomosis. The terminal 1 foot of the ileum and the large bowel up to the midtransverse colon were excised and an end-to-end ileotransverse colostomy was done. An ileostomy was then done in a loop in the right lower quadrant and the tube was brought out through the right lower quadrant wound. The right lower quadrant wound which was the site of a draining sinus and the transverse incision were closed except the skin and subcutaneous layers were tamponed open. A tube drain was placed down to the peritoneum in the lateral angle of the transverse incision as well as into the retroperitoneal tissue of the right lower quadrant.

Histological study showed a carcinoma of the cecum without extension of the tumor outside of the sinus tract, the wall of the cecum or into the lymph nodes.

Follow up. Patient was seen frequently and on October 5, 1939 (4½ years after resection of the

Fig. 2. Low power of one half of the appendix, showing the lumen free mucosa intact, submucosa normal except for fat replacement, which indicates an old inflammatory process, muscularis normal, subserosa presenting marked hyperemia and leukocytic infiltration.

A third operation was done October 11, 1933 (4 months and 9 days after drainage of abscess para-cecal, thought to be appendiceal in origin).

There was a manifest tumor attached to the abdominal wall penetrating the skin. Attached to the mass intra-abdominally were 2 loops of small intestine and 1 of sigmoid which seemed to be involved by the growth. The adjacent mesenteric lymph nodes were enlarged and obviously carcinomatous. There were small masses covering the uterus and also in the broad ligament, probably metastases. The aortic nodes were obviously metastatic.

Because of the marked extension along the lymphatic routes the lesion was considered to be hopelessly inoperable and no attempt was made to remove it or to resect the involved intestinal loops. Part of the growth that was protruding above the abdominal wall was coagulated, and a good deal of it was removed with the electrocautery. The wound was closed after a lymph node and part of the abdominal wall were obtained for histological examination, which showed adenocarcinoma on microscopic section followed by carcinoma of the cecum.

Patient was discharged in poor condition on the 3d postoperative day. She gradually deteriorated and died on December 3, 1933, a little more than 6 months after the first operation.

CASE 3. PH.435076. L.M. female aged 43, housewife, was admitted to Presbyterian Hospital after 3 weeks of suffering with a severe knife-like pain in the suprapubic region radiating to the right iliac region.

This pain kept recurring and was attributed to intestinal gas. For the previous 3 or 4 days the pain in the right lower quadrant had been increasing in severity and frequency and was associated with sweating, chills and fever during the night. Appetite was poor but there was no vomiting.

Physical examination revealed an obese female in great distress. In the right lower quadrant was a soft, oval, nontender, slightly movable mass of about 7 by 4 centimeters. There was no distention, redness or fluctuation. There was considerable muscle spasm, but no rebound tenderness.

The urine showed some albumen and red blood cells. A kidney-ureter-bladder plate showed no kidney stones. A cholecystogram revealed poor filling and evidence of gall stones. Impression acute appendicitis with abscess.

The first operation was performed November 5, 1934 and consisted of an appendectomy.

There was a small abscess at the base of the appendix containing about 5 cubic centimeters of pus. Distal to this the appendix lay embedded in a mass of firm tissue most of which was thought to be mesentery of the appendix. The mass was about 4 by 3 centimeters and was adherent to loops of small intestine and other structures unrecognized in the pelvis. It arose from a broad base of retroperitoneal tissue.

Through a McBurney incision the mass was exposed and an adjacent abscess cavity was entered. A Wertheim incision was made to expose the mass which

this admission. The fistula continued to drain. The patient died on June 2, 1938, about 2 years after resection of the cecum from recurrence of the carcinoma of the cecum.

Of the 13 cases previously reported between 1906 and 1946 and the 4 added by the author, 6 were females and 11 were males, ranging in age from 23 to 69 years with an average of 46.4 years.

The carcinoma of the cecum was recognized and resected by an ileocolicectomy at the first operation in only 4 instances. In all the other 13 cases there was a preliminary appendectomy or drainage of the right lower quadrant for an abscess or 'inflammation' in the region of the cecum.

In the 13 cases in which the carcinoma was not primarily resected there were 9 abscesses and in this group there were 5 persistent draining wound sinuses and 6 fecal fistulas, 1 of which developed after the 3d operation. It was the persistence of these draining wounds or fecal fistulas that led to subsequent biopsies of the sinuses or to exploration and finally to resection of the underlying carcinoma.

Histological studies revealed carcinoma of the cecum in 10 of the 17 cases. The 7 remaining presented only the surgeon's gross clinical diagnosis of carcinoma of the cecum. Generally there was no microscopic report on the appendix. Speese and Bothe reported an inflamed appendix. One of the writer's cases showed acute periappendicitis and another chronic appendicitis with acute inflammatory reaction. In one of the cases here reported the pathologist could not find the appendix in the ileocolicectomy specimen and it was presumed that it had become gangrenous and disappeared in the abscess stage.

In the majority of these cases a barium enema was not reported prior to the first operation, as most of the procedures were for acute appendicitis. However when it was reported it was usually inconclusive. In the later stages during the investigation of a persistent sinus or fecal fistula, there was usually found a filling defect, although in one of our cases the mass in the right lower quadrant was thought to be outside of the cecum. One cannot depend upon barium enema findings and should rely upon his clinical impression.

The follow up in these cases is entirely too inadequate to permit of any conclusions except that the results generally have been very disappointing and the outcome most unfortunate due in most instances to the failure to recognize the true underlying pathology at the first operation. The radical resection for carcinoma of the cecum was delayed generally for from 4 to 6 months after the initial appendectomy or drainage of an abscess or paracecal inflammation.

There were follow up reports in only 9 cases. These showed that 4 died of recurrence in from 3 months to 2 years after resection, 1 died of a stroke $5\frac{1}{2}$ years after resection, 1 died of intestinal obstruction and empyema 10 weeks after the first operation and 3 were living and well respectively 8 months, 3 years and 6 years after resection.

DIFFERENTIAL DIAGNOSIS

Since both benign and malignant lesions of the terminal ileum and cecum produce symptoms and physical signs closely resembling acute appendicitis, accurate differential diagnosis of these lesions is extremely difficult, particularly when acute inflammation of the appendix and carcinoma of the cecum co-exist. The proper diagnosis is facilitated, however, if one bears in mind the possibility that cancer of the cecum may occur in association with acute appendicitis, even in a young patient in whom cancer is not ordinarily suspected.

Intestinal obstruction is rare with cancer of the cecum, since the lumen is large and the fecal content is liquid. Anemia is often extremely marked in patients with cancer of the cecum and pernicious anemia should always be ruled out.

The entities which most commonly have to be differentiated from a cancerous mass of the cecum are appendiceal abscess with induration of the cecum and attachment of the omentum, regional ileitis with extension into the cecum, adhesions from previous operation in the right lower quadrant, tuberculosis of the cecum, usually secondary to pulmonary tuberculosis, occasionally diverticulitis, as reported by Christopher and Strode, and less commonly actinomycosis.

cecum) had no symptoms referable to the intestine. She had a cholecystectomy for acute cholecystitis and cholelithiasis in January 5, 1930.

About 6 years after her first operation for appendicitis and over 5½ years since the resection for carcinoma of the cecum, patient died suddenly of a stroke without having had any colon symptoms.

CASE 4. PH 485670, P. R., aged 69, female. First operation was in early November, 1935 in another hospital, where drainage of a paracecal abscess and ileotransverse colostomy were done for right lower quadrant pain of 24 hours duration associated with a mass which matted together the terminal ileum, and cecum and extended into the pelvis. The character of the mass could not be determined and the appendix was not visualized. A paracecal abscess was entered and a biopsy of the adjacent tissue was reported as inflammatory tissue. The abscess was drained and an ileotransverse colostomy was done. Convalescence was satisfactory and patient was discharged in 3 weeks. The wound closed but 2 months after the operation it broke down and discharged pus.

She was admitted to the Clinic at the Presbyterian Hospital on May 3, 1936 for continued pain distending sinus, and a mass in the right lower quadrant of 1 month's duration.

Physical examination revealed the abdomen soft, deep, and relaxed and presenting an irregular, tender, slightly movable mass in the right lower quadrant which filled the entire area from the iliac crest to the umbilicus. Barium enema revealed a well outlined cecum which seemed to be fixed. After a momentary delay a considerable amount of barium escaped into the ileum through an ileocolostomy. The mass in the right lower quadrant did not seem to be connected with the cecum. Re-examination by barium enema indicated that the mass, although in close proximity, was definitely outside the cecum.

A second operation was done on May 8, 1936 (about 6 months after the first operation) and consisted of a modified Mikulicz resection of the terminal ileum, cecum and ascending colon, and also an entero-enterostomy. A mass was seen just below the ileocecal junction with the cecum laterally and 3 loops of small intestine were adherent medially. A granulation tissue lined cavity with fibrous tissue periphery was present in the center of the mass. This cavity was continuous with the lumen of one of the small intestinal loops and probably also with the lumen of the cecum. No fecal material or pus was found in the cavity. A little gas escaped at one time from the opening into the small intestine. The liver could not be palpated because of dense adhesions. The appendix could not be distinguished but it was thought almost certainly to form part of the abscess cavity. A functioning ileocolostomy was present as done at first operation.

After excision of the old scar the cecum was mobilized. One could not be certain whether there was present a neoplastic or inflammatory process. I dissected one of the loops of small intestine from the

cecum an abscess cavity was entered and found to be continuous with the lumen of the small intestine. The other loops were then dissected free and a biopsy was taken from the wall of the abscess cavity for frozen section which was said to be "suspicious of carcinoma." The loop of small intestine which had been entered was resected and an end-to-end anastomosis was done. The cecum was mobilized further the blood vessels were ligated and divided and a Rankin clamp was applied to the terminal ileum and ascending colon, bringing them together where they were fixed to the peritoneum in the upper angle of the wound. The ileum and colon distal to the clamp were excised and the clamp was left *in situ*. A double soft rubber tube drain was placed down to the retroperitoneal space. Some small fragments of tumor or inflammatory tissue were undoubtedly left behind attached to the 3 loops of small intestine that were not resected and also in the retroperitoneal space.

Histological study showed carcinoma of the cecum with extension to the ileum and metastases to the abdominal wall. Section of 7 lymph nodes showed only chronic mesenteric lymphadenitis. The appendix could not be found anywhere either in or on the surface of the specimen. The tumor had infiltrated through the muscular wall of the cecum and into the outer circular layer of the adherent ileum.

A third operation was done on May 27, 1936,—an ileocolostomy side-to-side with Murphy button closure of colostomy and inversion of ileum. No evidence of tumor was seen. The parts of the ascending colon and ileum that represented a double barrel ileocolostomy were buried in adhesions and the opening was very small.

A transverse incision was made a little above the double barrel ileocolostomy opening. The colon and ileum were freed and an incision was made in the ascending colon and terminal ileum and a Murphy button was inserted into each opening and an anastomosis was made reinforced with Luken's gut. The terminal ends of the ascending colon, and ileum were isolated and inverted with 2 layers of sutures.

After operation the temperature continued between 101 and 102 degrees until the 30th day. She was discharged on the 63d day following the second operation (ileocolostomy).

Follow up August 20, 1936 wound was not healed and persistence of carcinoma was suspected. A large incisional hernia was present. Patient was referred for radiotherapy which was instituted on August 24, 1936 and up to December 15, 1936 she had 35 treatments, totaling 2400 rat units.

Patient was readmitted on March 10, 1937 for increasing abdominal pain with fecal fistula from the upper wound where the enterocolostomy with Murphy button was done. April 10, 1937 roentgenogram after the injection of the fecal fistula in the right abdominal wall showed apparent direct communication with the ascending colon.

On March 22, 1937 biopsy of the fistula showed no carcinoma. Patient was discharged to a convalescent home for terminal care on the 21st day after

this admission. The fistula continued to drain. The patient died on June 2, 1938, about 2 years after resection of the cecum from recurrence of the carcinoma of the cecum.

Of the 13 cases previously reported between 1906 and 1946 and the 4 added by the author 6 were females and 11 were males ranging in age from 23 to 69 years with an average of 46.4 years.

The carcinoma of the cecum was recognized and resected by an ileocelectomy at the first operation in only 4 instances. In all the other 13 cases there was a preliminary appendectomy or drainage of the right lower quadrant for an abscess or inflammation in the region of the cecum.

In the 13 cases in which the carcinoma was not primarily resected there were 9 abscesses and in this group there were 5 persistent draining wound sinuses and 6 fecal fistulas 1 of which developed after the 3d operation. It was the persistence of these draining wounds or fecal fistulas that led to subsequent biopsies of the sinuses or to exploration and finally to resection of the underlying carcinoma.

Histological studies revealed carcinoma of the cecum in 10 of the 17 cases. The 7 remaining presented only the surgeon's gross clinical diagnosis of carcinoma of the cecum. Generally there was no microscopic report on the appendix. Speese and Bothe reported an 'inflamed appendix'. One of the writers cases showed acute periappendicitis and another chronic appendicitis with acute inflammatory reaction. In one of the cases here reported the pathologist could not find the appendix in the ileocelectomy specimen and it was presumed that it had become gangrenous and disappeared in the abscess stage.

In the majority of these cases a barium enema was not reported prior to the first operation as most of the procedures were for acute appendicitis. However when it was reported it was usually inconclusive. In the later stages during the investigation of a persistent sinus or fecal fistula, there was usually found a filling defect, although in one of our cases the mass in the right lower quadrant was thought to be outside of the cecum. One cannot depend upon barium enema findings and should rely upon his clinical impression.

The follow up in these cases is entirely too inadequate to permit of any conclusions except that the results generally have been very disappointing and the outcome most unfortunate due in most instances to the failure to recognize the true underlying pathology at the first operation. The radical resection for carcinoma of the cecum was delayed generally for from 4 to 6 months after the initial appendectomy or drainage of an abscess or paracecal inflammation.

There were follow up reports in only 9 cases. These showed that 4 died of recurrence in from 3 months to 2 years after resection, 1 died of a stroke 5½ years after resection, 1 died of intestinal obstruction and empyema 10 weeks after the first operation and 3 were living and well respectively 8 months, 3 years and 6 years after resection.

DIFFERENTIAL DIAGNOSIS

Since both benign and malignant lesions of the terminal ileum and cecum produce symptoms and physical signs closely resembling acute appendicitis accurate differential diagnosis of these lesions is extremely difficult particularly when acute inflammation of the appendix and carcinoma of the cecum coexist. The proper diagnosis is facilitated however, if one bears in mind the possibility that cancer of the cecum may occur in association with acute appendicitis even in a young patient in whom cancer is not ordinarily suspected.

Intestinal obstruction is rare with cancer of the cecum since the lumen is large and the fecal content is liquid. Anemia is often extremely marked in patients with cancer of the cecum and pernicious anemia should always be ruled out.

The entities which most commonly have to be differentiated from a cancerous mass of the cecum are appendiceal abscess with induration of the cecum and attachment of the omentum, regional ileitis with extension into the cecum, adhesions from previous operation in the right lower quadrant, tuberculosis of the cecum usually secondary to pulmonary tuberculosis, occasionally diverticulitis as reported by Christopher and Strode and less commonly actinomycosis.

Generally an inflammatory mass in the right lower quadrant is more fixed to the surrounding structures, while a cancerous lesion is fairly freely movable in the early stages although with perforation and abscess formation it is often fixed. The inflammatory mass is less circumscribed and less easily delineated than the neoplastic process. The cancerous lesion develops more gradually while the inflammatory process arises more rapidly. The inflammatory process presents more localized tenderness and muscle spasm except when there is perforation of the tumor with abscess formation. Fever and leucocytosis are usually more marked with an inflammatory lesion except with perforation of the cancer.

COMMENT AND CONCLUSIONS

The preoperative diagnosis of acute appendicitis and periappendicitis in association with carcinoma of the cecum is extremely difficult and is rarely made. Too frequently it has not been made at the first operation and therefore the indicated radical surgery has been unduly delayed.

Barium enema should be done in cases suspected of harboring a carcinoma of the cecum but too much dependence cannot be placed in the interpretation as small filling defects can be easily overlooked or the findings misinterpreted.

The persistence of a fecal fistula for more than 6 to 8 weeks following an operation for pathology in the cecal area should make the surgeon acutely conscious of the possibility of an underlying cancer of the cecum and should indicate further operative intervention.

Every effort should be made if the condition of the patient permits, to explore adequately the entire cecal area to determine the presence or absence of a carcinomatous lesion and to do a radical resection of the cancer under most conditions.

The presence of pus or abscess cavity in the vicinity of the cecum should not be a deterrent to satisfactory exploration. The patient has

already developed considerable natural immunity as the result of the abscess formation, and one may lose a golden opportunity to resect a cancer of the cecum because of the presence of pus.

Adequate biopsy should be taken if the surgeon cannot within reasonable limits, make a clinical diagnosis of cancer. A frozen section should be made if possible while the abdomen is still open.

A cecotomy should be done for palpation of the inner surface of the cecum where there is doubt about the diagnosis.

With markedly improved and selected anesthesia the free use of whole blood and the various antibiotics, together with proper attention to electrolyte balance and the employment of the Miller Abbott tube for purposes of decompression, radical surgery of the right colon is less dangerous than leaving in situ an unrecognized cancer of the cecum.

Early and radical operation is the only hope of cure in these cases of carcinoma of the cecum with acute appendicitis.

THE CORRECTION OF STRESS INCONTINENCE BY SIMPLE VESICourethRAL SUSPENSION

VICTOR FRAY MARSHALL, M.D. F.A.C.S. ANDREW A. MARCHETTI, M.D., and
KERMIT E. KRANTZ, M.D. New York, New York

A PROCEDURE for the correction of urinary stress incontinence has been devised which has given results approximating and often surpassing those which follow the commonly used operations. A description of this new attack upon an old problem is given as well as an account of a test devised to facilitate the selection of cases in which the outcome of treatment is likely to be successful. This procedure has been carried out on 50 patients to date. Thirty-eight cases were of the usual variety of stress incontinence in females and 25 of these had previously had a total of 40 standard gynecological operations without relief of this distressing condition. The remaining 12 patients were treated for unsatisfactory urinary control due to a variety of causes.

The basic plan of this procedure was derived from a study of vesical dysfunction following removal of the rectum (11). A high incidence of disturbance in the lower urinary tract chiefly retention followed excision of the rectum by either the abdominoperineal approach or the perineal route alone yet the incidence was low following operations omitting the perineal dissection. Traditionally this dysfunction has been ascribed to damage of nerves, but in this study no specifically neurological change could be demonstrated. Furthermore, transurethral revision of the vesical outlet in those patients having persistent retention after perineal rectal removal provided more satisfactory results than are usually obtained in instances of established neurogenic bladder. On the other hand transurethral resection after rectal excision was less satisfactory than in cases of simple prostatism. Accordingly it seemed apparent that a major factor producing retention after per-

neal excisions existed which was not neurological and which was not pure prostatism. An observation that most of the patients with this complication had mobility and marked sagging of the vesical base and outlet suggested that lack of elevation and fixation might be this unrecognized factor. In some cases firm upward pressure on the perineum with a fist or harness would provide temporary elevation and fixation and these patients could thereby void satisfactorily. In fact one patient declined transurethral surgery when he found that perineal support on voiding permitted emptying and relieved overflow in continence. From time to time mysterious cases appeared in which after removal of the rectum a transurethral prostatectomy relieved retention only to result in incontinence! Finally the following case seemed to integrate these observations and suggestions.

L. W. M. H. history No 70735, a 54 year old male had complete urinary retention following abdominoperineal removal of the rectum. Neurological changes in the urinary apparatus could not be demonstrated. Two transurethral resections resulted in total incontinence even though the external urethral sphincter had not been damaged. Perineal pressure would provide good control. Simple suprapubic suspension of the vesical outlet by suturing to the pubis immediately and completely corrected his urinary control which has remained normal for a period of 46 months.

By analogy the knowledge gained from the study of these rectal cases was applied to the problem of the common stress incontinence of females. A simple operative elevation and fixation via the suprapubic route was planned but first a prognostic test was devised based particularly upon the observations regarding sagging of the vesical outlet and the effect of perineal pressure. This test provides simple temporary elevation and fixation of the vesical outlet as an evaluation for each case considered for operation. Its value was promptly appreciated because a successful result from

Fig. Operative area exposed and urethra U separated from symphysis. S R, rectus muscles, B bladder P peritoneum I upper surface of vagina

the new operation was rarely obtained if the preoperative test was unfavorable. Further more the cause of some failures following the suspension and standard operations for incontinence can be revealed by this trial procedure.

The test was made by filling the bladder with 250 cubic centimeters of saline and observing the patient's urinary control while coughing and straining in the prone and standing positions. After the bladder was refilled to 250 cubic centimeters the same procedures were repeated with the exception that elevation and fixation of the vesical outlet was provided in the following manner: A wheel of novocain which was made in the vaginal wall at a point estimated to be under the interureteric ridge was grasped with an Allis clamp and held firmly upward toward the umbilicus not permitting downward movement on coughing and straining. If this elevation and fixation provided good urinary control the test was considered favorable. As accessory evidence pulling the vesical base downward toward the introitus caused poorer control. Use of the clamp attached to the wheel was more accurate than providing the support with a finger because the examiner

could be more certain that control was not afforded merely by compression of the urethra or vesical neck. Actually a finger just anterior to the cervix can provide the elevation and fixation without compression of the outlet if carefully done. Pressing the rectum posteriorly usually made control worse. Having the patient stop and start the urinary stream while the upward immobilization was maintained would indicate by the caliber of the stream whether or not the lumen of the outlet was constricted as well as further indicating the degree of control obtained.

The first female patient (I. B. M. H. history number 58,136) selected for simple suprapubic elevation and immobilization of the vesical neck and urethra was 31 years old complaining of constant painless leakage of urine from the urethra for years except when in bed. Even though pads were worn constantly she was required to change her clothing at least twice daily. A mild cystourethrocele was present. Urinalysis and cystoscopy were unremarkable. No psychiatric nor psychosomatic disorder was evident. The previously described test was favorable.

On June 8, 1944 under general anesthesia, the following operation was performed and the technique has not been altered essentially in subsequent cases. A No. 24 F Foley catheter with a 30 cubic centimeter balloon was placed into the bladder transurethrally and the bag inflated. The patient was arranged in Trendelenburg position with emphasis on the elevation of the pelvis proper rather than merely lowering the head of the table and bending the knees downward (19). A suprapubic incision was made to expose the space of Retzius widely. Light pressure on the top of the bladder and the urethra with a sponge on ring forceps readily separated the bladder and urethra from the posterior surface of the pubis and rectus muscles down to 1 centimeter or less of the external urethral meatus. The suspensory attachments between these structures were extremely delicate bearing only the faintest resemblance to the tough puboprosthetic ligaments of the normal male. An assistant's fingers in the vagina aided the palpation of the catheter and balloon which corresponded to the urethra and vesical neck respectively. Three sutures of No. 1 chromic catgut were placed equidistant from each other on either side of the urethra. The su-

turing needle was inserted deeply into the upper wall of the vagina adjacent to the urethra and through the lateral wall of the urethra, caution being exercised to avoid entering the urethral lumen. A double bite was taken to insure a secure hold and also to place eventually as large an amount of tissue as possible in apposition to the pubis. A similar suture was then placed on either side of the vesical outlet in the angle between the balloon and the catheter after the balloon had been pulled down to mark the outlet. When upward traction was made on the long ends of these eight sutures the urethra and vesical neck were lifted away from the introitus which change was particularly noticeable by the assistant who had two fingers in the vagina. At this stage additional sutures were placed at points of advantage lateral to the urethra where the vaginal wall apparently sagged that is one additional suture on each side but the number has varied according to circumstances in subsequent cases. With a curved round-edged needle the long ends of these sutures were placed securely through the periosteum of the pubis, especially into the cartilage of the symphysis whenever feasible. The locations for these sutures in the pubis or rectus muscles when indicated were carefully selected in order that when the sutures were tied they would move the urinary passage upward and backward from the introitus. Upward displacement by the assistant's fingers in the vagina aided the selection of these sites and avoided undesirable tension until a sufficient number of the sutures had been tied. Thus the space of Retzius was closed and a wide area of the superior surface of the urethra and vesical neck opposed to the symphysis and the posterior surfaces of the rectus muscles. Additional sutures were now placed in the musculature of the lower and lateral portions of the bladder with their long ends in the posterior parts of the rectus muscles and tied to further pull the bladder anteriorly into the space of Retzius. One small rubber drain was inserted in the wound for the same reason that chromic catgut sutures were used instead of silk, namely better to protect the field of operation should urinary leakage occur as a result of any of the sutures having

Fig. 2. Lowest suture on either side in place.

penetrated the urinary lumen. The abdominal wound was closed in a routine manner.

Inspection following the procedure revealed no cystourethrocele and only the barest motion of the urethra on straining. With the patient lying horizontally the long axis of the urethra was close to a 45 degree angle with the floor instead of parallel as before the operation. The external urethral meatus appeared retracted inward and upward. The Foley catheter was attached to the thigh by adhesive tape in order to absorb any accidental traction contrary to the purposes of the operation. The urine contained gross blood for 2 days after operation. The drain was removed on the second postoperative day and the catheter on the seventh.

In the 34 months following operation this patient has not worn a perineal pad or other protection and has not been incontinent. She has worked moving office files without urinary incontinence and can safely cough and sneeze. In addition there has been no recurrence of the cystocele. The urinary stream is of large caliber and forceful. Two hundred fifty cubic centimeters of water placed in the bladder is retained and voided normally without leaving any residual. She voids on the average of five times a day and occasionally once at night.

In selecting additional candidates for this operation the value of the previously described test was not only emphasized but certain other conditions frequently required exclusion by specific measures. When stress

incontinence coexisted with other diseases which may cause urinary dysfunction the differentiation of the degree of trouble attributable to each disorder separately was often difficult. The commonest disease confused and coexistent with stress incontinence was chronic nonspecific urethritis with or without cystoscopically observable trigonitis. This frequent coexistence of incontinence and urethritis suggested that their relationship was etiologically more than fortuitous particularly as the correction of one often decreased the symptoms due to the other. Generally speaking the urethral irritation was the more easily treated of the two. Those patients with urethritis as the major factor producing their complaint were usually found on careful questioning and observation to have marked urgency and frequency rather than actual loss of the mechanics of retention. They had the desire to void which might be sudden and irresistible and then wet themselves. They however had some warning. The truly incontinent patients would wet themselves without warning (except as only experience might have taught them that certain activities usually caused leaking). A therapeutic trial of slowly progressive urethral dilations to open the ducts of the urethral glands, followed by instillations into the bladder and urethra of 1:5000 silver nitrate at weekly intervals, and accompanied by two sitz baths daily of 15 minutes each usually produced marked improvement by the second or third week if urethritis was a major factor causing symptoms. The source of such urethral infection was sometimes evident in the vagina, cervix, perineal ducts and glands or in a urethral caruncle. Correction of these disorders, when they existed, was occasionally of paramount importance. Other more generally recognized causes of cystitis or urethritis were excluded particularly if the urinalysis was abnormal, tuberculosis, neoplasms, urethral obstructions, fistulas, renal infections, etc. Hunner's ulcer usually produced a characteristic history of pain with bladder distention and cystoscopy established that diagnosis. Fully developed neurogenic bladders were usually suspected from the history and general examination but in the incipient stages

the differentiation from non neurogenic incontinence was difficult. Occasionally females were found to have large residual urine and thereby overflow or paradoxical incontinence—not a weakness of the retaining mechanism. Cystoscopy, trial therapy for urethritis, a simple neurological examination, complete urinalysis, estimation of renal function and finally the inquiry into the patient's psychological reactions seemed important in the selection of candidates for this new operation in addition to the described test. It will be pointed out later that some of our failures can be attributed to poor selection rather than to the operation itself which is not designed to cure all types of incontinence.

Following the first 2 cases just described an additional 48 patients, 4 male and 44 female, have been operated upon. They had various lesions causing poor urinary control and various bases for selection. The results have been excellent in 32 of the total number of 50 patients, good but not excellent, in 6, improved but not satisfactory, in 3, failures in 9, but none had worse control than before operation. This gross tabulation does not present the true value of the method though it does indicate the existence of limitations. If the results for those cases preoperatively selected as favorable by the advised study are tabulated the effectiveness of the procedure is apparent: of 44 so selected, 36 (82%) are excellent results, 3 (7%) are improved and 5 (11%) are failures at the time of this writing. Furthermore the reason for not obtaining excellent results is obvious in 4, sutures insecurely placed (the first attempt of an operator not familiar with the details of the procedure), excessive scarring which did not permit elevation by the suprapubic route alone due to lymphogranuloma in 1 case and due to previous surgery with infection in another and wound infection. The cause of a fifth incomplete result is uncertain. The patient stated she was greatly improved when seen in our follow-up clinic but when seen later outside the hospital said she still leaked and she will not return to the clinic for evaluation. After leaving the hospital 3 patients' control became weak from cause unknown.

except in 2 of these a partial recurrence followed unusual straining

The largest single group in the series is perhaps the most important not only because the best results were obtained but also because it represents the commonest variety of incontinence. The group consists of 38 female patients having the common variety of so called stress incontinence that is the type generally recognized as being due to relaxation especially following deliveries or the endocrine changes of aging, the variety considered suitable for such standard operations as those devised by Kelly, Kennedy, Aldridge, Studdiford and others. Furthermore, 25 (66%) of the patients in this group had had 40 standard gynecological operations of types which are recognized to provide good control routinely, but which had failed in these cases. Twenty nine (76%) of these 38 patients had control so poor that urine leaked out of the urethra even while in bed or leakage was so constant when up and about that only occasionally did they retain enough to void a stream. These 29 could be termed 'soakers'. Eight others were protection for their clothing or changed clothes daily because of wetting at least 5 days out of 7. One patient had only mild difficulty but poor control was demonstrable the suspension operation being done incidental to the removal of an ovarian cyst. All 38 patients came to the hospital to request treatment to improve their control. Preoperatively 37 were considered suitable for the new operation. The thirty-eighth case was an error in selection and this error was the obvious cause of failure. The patient had had 2 vaginal operations to gain control which resulted in a urethra and vesical neck so scarred as to contain almost no functioning muscle. The walls of these structures were paper thin apparently consisting of only a mucosal lining inside and vaginal epithelium outside. The urethra was approximately 1 centimeter in length. The supportive test was equivocal preoperatively and postoperatively this trial procedure remained unfavorable. Only broad firm compression of the vesical outlet (not merely the urethral remnant) against the pubis permits retention of more than a few cubic centimeters.

Fig. 3. Diagram of sites for sutures. Dots are for sites along urethra and vesical neck. Crosses, for sites in lower bladder and vagina. Other sutures are often taken as explained in text.

Of the whole 38 cases of this female group with so called stress incontinence 28 or 74 per cent have entirely satisfactory urinary control at the time of this writing from 1 to 35 months after operation. By entirely satisfactory is meant that the patient does not wear protection for her clothes, does not even get damp in spite of pursuing her usual activities and voids without difficulty. Seven 18 per cent have evident improvement but the result is not completely satisfactory. One of these 7 is a 72 year old female who had normal control until a cystocele was repaired after a radical vulvectomy for carcinoma. The cystocele was corrected but heavy scarring around the vagina resulted which seemed to hold the urethra and vesical neck down. After the suprapubic suspension she no longer leaked in bed voided regularly and usually stayed dry for 20 to 40 minutes after each voiding during the day—all in direct contrast to her preoperative status. However leakage occurs so easily she must wear protection during the day. A satisfactory pessary cannot be fitted but manual support still improves control if enough pressure is used to release the downward tension of the vaginal fibrosis. Four others in this group of improved but not satisfactory results show approximately the

Fig. 4. Sagittal section showing the four para-urethral sutures on the left.

same degree of improvement as in the case just described they do wet themselves, yet not enough to be soakers. Two patients are personally pleased. The other two while improved are not personally pleased by the amount of control returned. All considered it can be academically stated that 92 per cent of the patients postoperatively show a change in urinary control definitely for the better. Three 8 per cent of the 38 are complete failures, one being due to improper selection as described. (The cases of incontinence due to lymphogranuloma and transurethral resection of the vesical neck are not included as being the usual type of female urinary incontinence though the cases have items in common.)

These results compare reasonably well with reports in the literature concerning the results of other operations designed for the cure of this type of incontinence. Kelly and Dumm reported 20 per cent failures with the now famous Kelly operation. The results of 105 vaginal operations for obtaining urinary control were reported by Watson as satisfactory

in 65.7 per cent, improved in 21.9 per cent, and unimproved in 12.4 per cent. Berkow using an operation consisting of advancement of the urethral meatus and distal urethral reefing had 2 failures in 21 attempts (9 per cent). Kennedy (7, 8, 9) after a detailed study of the anatomy and physiology concerning micturition devised a vaginal operation similar in part to Kelly's plans with which he has had only 7.1 per cent failures. Studdiford using Aldridge's fascial sling operation had 4 failures in 15 attempts (26.6 per cent) but with Studdiford's modification 27 of 30 were successful (10.0 per cent failures). Te Linde reports 90.3 per cent well, 5 per cent improved and 3.5 per cent unimproved with a Kelly type procedure used selectively 249 times.

The details of the follow-up of cases, including definition of terms and time elapsed since operation are seldom indicated in the literature. Most of the results reported are immediate outcomes, yet late recurrences are recognized not to be rarities. One author (14) reported 45.5 per cent recurrence of poor urinary control when 78.4 per cent had been

Fig 5 Same as Figure 4 except sutures tied—diagrammatic, as actually lies space remains between origin and insertion of sutures.

satisfactory immediately following anterior colporrhaphy. In the present series 3 recurrences of poor control have appeared since discharge from the hospital 2 within 6 months and 1 later. Onset of recurrence was with lifting or severe coughing in each case. The other unsatisfactory results were evident upon removal of the catheter after operation. The follow up time between operation and the last definite record regarding urinary control varies from 1 to 35 months with 28 having been followed 6 months or more, 16 one year or more and 5 two years or more. All patients have been seen since discharge. The effect of pregnancy and especially vaginal delivery upon the suprapubic suspension has not been tested, but from general considerations we advise these patients against pregnancy.

A review of the literature might lead one to believe that the standard gynecological operations for incontinence rarely if ever made the patients condition worse yet experienced gynecologists are aware of such complications as vaginal fistulas, ureteral fistulas, ureteral ligation and poorer control. None of these occurred in the present small series but because of the operative approach the incidence

of these complications should be exceedingly small. One patient's urethra was so adherent from 4 previously unsuccessful operations that an opening was inadvertently made into it which was sutured. A small amount of urinary drainage occurred suprapubically for 7 days after which the fistula closed spontaneously. This patient had normal control 6 months later. Two psychiatric patients with both enuresis and partial incontinence were cured of the incontinence but not of the enuresis (though one wet the bed only once in a year after operation). Often the patients had frequency and urgency until the irritative effects of the indwelling catheter and infection were overcome after operation. Two wound infections occurred both were mild and neither required additional drainage but in one of these a hernia later developed. One other patient has a ventral hernia but this is apparently the result of a previous suprapubic operation. Two hematomas occurred but did not impair the result. One patient had an attack of acute cholecystitis during her hospital stay and one had pains suggesting osteitis pubis which promptly subsided. There were no deaths.

colostomy reduced the residual to 75 to 200 cubic centimeters but a wound infection disrupted the suturing with resultant return of the same degree of retention.

The case of a male patient having a successful suprapubic suspension after removal of the rectum and transurethral resections was outlined at the beginning of this article. One additional case, almost exactly similar has shown improvement the patient is pleased but he does leak at times so the result is classed as improved but not satisfactory.

Of three male patients having unfavorable supportive tests preoperatively only one obtained improvement though none became worse. Two were incontinent after suprapubic prostatectomies done elsewhere and one after accidental transurethral incision of the external sphincter by us.

DISCUSSION

The word *new* is used advisedly in referring to this simple suprapubic vesicourethral suspension. As far as we can determine the procedure as a whole is new for *incontinence*. Hepburn (4, 5) and later Miller (12) used a similar technique for *prolapse* of the female urethra, but not primarily for the correction of incontinence. However Miller (12) remarked that 1 of his 3 patients had better control following operation so that the procedure might cause improvement. Others notably Pernin and Williams have sutured the top of the vesical outlet to the symphysis and thereby improved control. Apparently they did not suspend and fix the urethra also. Suprapubic Kelly type plications some successful have been reported by Furniss and others. Suprapubic transvesical operations (10, 22) may have had part of their success due to the unrecognized adherence of the vesical neck to the symphysis postoperatively. The mere conception of elevating and fixing the outlet is by no means new but surprisingly is frequently ignored.

The exact mechanism by which this operation improved urinary control in most of the selected cases is not entirely understood. However simple elevation and fixation of the vesical outlet and urethra seem to be the only

significant change that can result from the technique. No muscles are plicated and no hammock like support is constructed under the sphincter. Most sphincters have two or more relatively firm attachments and perhaps the major achievement of the operation is providing such attachment. The recent work of Rose particularly stresses the importance of these attachments in contributing to normal urinary control.

SUMMARY

The development of a new operation for certain types of urinary incontinence has been described. A preoperative test consisting essentially of temporary elevation and fixation of the vesical neck and urethra has permitted the selection of those candidates who have an excellent chance for improvement by the operation and which at the same time seems to indicate those whose postoperative result will not be good. The operation is a simple elevation and immobilization of the vesical neck and urethra by suturing them to the pubis and rectus muscles. Of 44 suitable cases excellent results were obtained in 36 (82%) significant improvement in 3 (7%) and no improvement in 5 (11%). The causes of most of the failures seem evident and are discussed. The most significant group reported consisted of 25 patients with the common variety of female stress incontinence which had failed to be corrected by one or more standard gynecological procedures for incontinence. Of these 25 patients 19 have normal control from 1 to 35 months after this new operation with 21 having been followed 6 months or more. Poorer urinary control did not result in any instance.

It is not the intent of this presentation to advocate this operation to the exclusion of others. As can be seen the procedure is followed by failures in 10 to 15 per cent though careful use of the described preoperative test should permit better selection and thereby fewer failures.¹ The intent is to emphasize two principal points: first that elevation and

¹Since preparation of this article an additional 20 patients have been operated upon by this technique. Nineteen have excellent results and the follow-up is incomplete in the other case.

fixation of the vesical neck is a major factor in the maintenance of urinary control and second that this operation is worthy of trial in selected cases in which previous surgery has failed

INTRAMEDULLARY BONE FIXATION IN PATHOLOGIC FRACTURES

J. L. EHREHAFT, M.D., and R. T. TIDRICK, M.D., F.A.C.S. Iowa City, Iowa

IT is the purpose of this paper to report our experience with the Kuentscher intra medullary nail in the treatment of pathologic fractures of the long bones. Numerous references have appeared in regard to the use of the Kuentscher nail for the treatment of simple and compound fractures (1, 3, 4, 5, 7). Infrequent mention has been made of its use in the treatment of pathologic fractures (2, 4, 6). It is not within the scope of this paper to review the reports which have accumulated regarding its use in the general treatment of fractures. However, as we gained experience with this method in the treatment of simple fractures in nonunion and other complicated fractures of long bones, we observed that the method has singular value in overcoming the troublesome problems associated with pathologic fractures and justify this additional report to the already extensive literature on the subject.

The ideal method of internal fixation of bone would be one in which the necessity for open reduction at the fracture site could be circumvented. The fixation should be such that immobilization in a plaster cast would be unnecessary. Weight bearing and free motion of the adjacent parts should be permissible at the earliest possible time. Finally, there should be maximal opportunity for callus formation and minimal interference with normal bone healing. These tenets apply particularly to the peculiar problems of pathologic fractures, although all are not always attainable. Thus, for example, the fact that such patients are sometimes in the terminal stages of their illness makes it undesirable to immobilize the extremity in plaster. In such instances, intramedullary nailing makes it possible for patients with generalized carcinoma to return to the care of the family and insofar as the fracture is concerned to be

pain free and comfortable for the remainder of their lives. Again, the factor of facilitating nursing care in these patients is an important one.

While the above remarks are not altogether applicable to Paget's disease (osteitis deformans), the peculiar mechanical conditions imposed by the brittle bones in this disorder, the high frequency of transverse fractures, and the occasional complication of delayed union render this method very useful in attaining a satisfactory mechanical reduction. In our experience with Paget's disease, early healing of the fracture followed in every instance.

Technique. The following remarks pertain to the technique of reduction and internal fixation of pathologic fractures of the femur, since in every instance of this series this was the bone involved (3, 5, 7). In each instance, the patient was placed on the fracture table in traction and in lateral decubitus position. In 5 instances, general anesthesia (pentothal and nitrous oxide) was employed, and in the remaining 5, spinal anesthesia was used. The affected extremity was slightly flexed at the hip and adducted, thus providing easy access to the region of the greater trochanter. A linear vertical incision sufficient to allow drilling of the bony cortex was made at the trochanteric fossa. When occasion demanded, this incision was extended distally in order to permit open reduction at the fracture site. In 8 instances, open reduction at the fracture site was effected, and on each such occasion, biopsy was obtained. A guide rod was introduced through a drill hole and passed through the medullary cavity across the fracture site, fixing it. The nail was then driven over the guide and the guide removed. The wound was closed with interrupted silk. The course of reduction and fixation was followed by the use of portable roentgenograms taken in the operating room in both the anteroposterior and lateral planes.

From the Department of Surgery, State University of Iowa, University Hospitals, Iowa City, Iowa.

Fig. Case. Roentgenogram taken April 6, 1947 shows pathologic fracture through femur (a), J by Paget's disease; b, after insertion of intramedullary nail, April 18, 1947; c, 3 months after insertion of intramedullary nail, July 2, 1947.

CASE REPORTS

CASE E.T. A 52 year old laborer was admitted to the surgical service on April 16, 1947 with the complaint of a broken left thigh of 3 days' duration. He also gave a history of periods of unconsciousness, occurring intermittently for the past 7 years. The patient stated that he had had a Colles' fracture of both wrists in 1933, a fracture of the right femur in 1937 and a fracture of the left tibia and fibula in 1945. There was inadequate history of trauma with these fractures. Three days prior to this admission he experienced another episode of unconsciousness and fell to the sidewalk, which resulted in the present fracture.

Examination on admission showed a well developed and well nourished white male, not acutely ill. The left lower extremity was in Thomas splint traction. The chest and heart were normal to percussion and auscultation. Inspection of the patient's fingers showed definite evidence of clubbing and pulmonary osteoarthropathy. Inspection of the patient's left thigh showed a moderate amount of swelling and subcutaneous extravasation of blood. There was a false point of motion about the mid-shaft of the left femur and point tenderness in this area. Roentgenograms showed an oblique fracture through the shaft of the femur at the junction of the middle and lower one-thirds. The cortex of the bone about the fracture site appeared unusually thick while the bone about the knee joint appeared atrophic. The appearance was suggestive of a pathologic fracture through an area of Paget's disease. A roentgenogram of the chest showed generalized pulmonary fibrosis.

On April 17, 1947, under spinal anesthesia, a Kuntscher intramedullary nail was inserted into the left femur. Open reduction at the site of fracture was not necessary in this instance. Postoperative roentgenograms showed the intramedullary nail in place in the medullary canal across the fracture site with slight anterior tilting of the distal fragment. The anteroposterior view showed excellent alignment. The patient's postoperative course was uncomplicated. He was able to sit up in a chair on the 3rd postoperative day and was permitted to bear weight on the extremity with the help of crutches 1 week after the operative procedure. He was discharged on the 14th postoperative day with the instruction not to bear weight without the aid of support.

He was seen again on June 10, 1947 at which time examination of the left lower extremity showed a normal range of motion of the hip and knee joints. The patient had been able to walk with crutches or with the aid of one crutch for several weeks. Roentgenograms taken at this time showed union at the fracture site, however the healing did not appear complete. He returned again to our service on July 22, 1947 at which time good union and heavy callus formation was seen in the roentgenograms. It was observed that there was slight bending of the nail. The patient had been ambulatory.

CASE 2 C.F., a 60 year old man was admitted to the surgical service on April 25, 1947 with the complaint that 24 hours before admission he suffered a fracture through the right thigh. He stated that he had been sitting and shifting his right lower ex-

tremity when a spontaneous fracture occurred. The patient gave the history that during September 1944 he had what was thought to be a neoplasm involving the alveolar ridge of the left maxilla which was resected at that time. He also had bilateral radical neck dissection during September 1944. In September 1945 the patient suffered a fracture through the lower third of the right femur. The diagnosis at that time was a pathologic fracture. It was treated by open reduction. A biopsy was taken which showed probable metastatic carcinoma in the femur. This oblique fracture was treated by his local physician by application of a metal band application of a plaster cast and intensive roentgen therapy. Following this procedure he got along well for 1½ years until 24 hours before his admission to this hospital.

Examination on admission revealed an operative intraoral defect of the left maxilla communicating with the nasal cavity. Bilateral surgical scars were present over the neck. Inspection of the right lower extremity showed deformity, swelling and tenderness about the mid femoral region. A scar was present over the lateral aspect of the thigh just above the knee. Roentgenograms of the right femur revealed a pathologic fracture at the junction of the proximal and middle one thirds with medial displacement of the distal fragment. There was evidence of an old healed fracture approximately 10 centimeters distal to the present fracture. There was a metal band about the old fracture site. The bone appeared firmly united. Extensive search for an other primary site for the possible bone metastasis to the right femur revealed no demonstrable lesion. It was thought that the left maxilla was the site of the primary neoplasm.

On April 26 1947 under spinal anesthesia, a Kuentscher type nail was inserted without undue difficulty. Open reduction at the fracture site was not necessary in this instance. The patient's postoperative course was quite uneventful and there was immediate relief of pain at the fracture site. He had a relatively stiff knee preoperatively perhaps as a result of the prolonged immobilization in a cast during his previous fracture episode. Postoperative roentgenograms showed the intramedullary nail in place with satisfactory position and alignment of the fracture involving the mid-shaft of the femur. The patient was discharged on the 13th postoperative day.

The patient returned on July 15 1947. Examination revealed the right thigh to be strikingly increased in diameter mostly around the site of the previous fracture. Roentgenograms revealed no evidence of union and showed definite extension of the neoplastic process. The patient was treated with irradiation with some improvement. He returned again on September 26 1947 at which time the right thigh was greatly increased in circumference with a mass involving most of the thigh but the patient was still quite comfortable and pain free. Roentgenograms on September 26 1947 showed no evidence of bony union at the recent fracture site

Fig. 2. Case 2. a, Pathologic fracture through an area of metastatic carcinoma, April 26, 1947. b, after insertion of intramedullary nail May 6 1947.

and there appeared to be more destruction of bone at the fracture site from the known neoplasm. Roentgenograms of his chest revealed no evidence of neoplastic metastasis. He was again given intensive irradiation therapy and on October 13 1947 biopsy specimens of tissue from his right thigh were taken which revealed only hyalinized muscle and fibrous tissue. During this hospital stay the patient developed some rectal bleeding. Examination revealed several small nodules about 2 centimeters superior to the anal margin. A biopsy was made from these nodules and sections showed probable malignant neoplasm, the origin of which could not be stated definitely. At the time of discharge from the hospital the patient had extensive destruction of the right femur, the intramedullary nail still holding the ununited fracture ends in satisfactory position.

CASE 3. M.D. A 56 year old man was admitted to the surgical service on March 17 1947, a few hours after a tractor accident in which he suffered a compound fracture of his right tibia and fibula and a fracture of his left femur and multiple contusions. Roentgenograms showed a subtrochanteric fracture of the left femur through an area of bone which appeared to be involved by Paget's disease. Roentgenograms of the right tibia and fibula showed a transverse fracture of the upper portion of the tibia and a transverse fracture of the fibula at the junction of the lower and middle one thirds.

The patient was treated in balanced traction with a Steinmann pin through the lower femur on the left and his right extremity was placed in traction on a Boehler frame with a Steinmann pin through the os calcis. Clinical evidence of gas gangrene developed in the compounded injury of the right lower extremity however under intensive treatment the infection remained localized. Roentgenograms taken

Fig. 3. Case 3. a, Refracture 3 months after initial injury of femur involved by Paget's disease, June 7, 1947; b, 6 months after insertion of intramedullary nail, August 4, 1947; c, 9 months after insertion of intramedullary nail, March 8, 1948.

On May 7, 1947, evidence of callus formation around the subtrochanteric fracture of the left femur. The patient's right lower extremity was then placed in a long-leg cast for immobilization of the fracture of the tibia and fibula. On June 11, 1947, some drainage was noticed exuding around the Steinmann pin which had been placed for traction through the left femur. While being returned to the ward after having roentgenograms taken, the patient twisted his left hip and felt a snap in the area of the subtrochanteric fracture of the left femur. Examination revealed a re-fracture through the previous fracture site. It was then decided to perform an internal fixation of the left femur and on June 20, 1947, open reduction at the fracture site was performed under spinal anesthesia. A Kuntscher type nail was inserted into the left femur, fixing the fracture adequately. A biopsy of bone was taken from the fracture site which showed bone compatible with Paget's disease. Following this operative procedure the patient's course was uncomplicated. The relief of pain after internal fixation was immediate and the patient was quite comfortable. He was discharged on the 17th day following insertion of the Kuntscher nail, the right lower extremity having been incorporated in a long-leg cast for immobilization of the fractures of the tibia and fibula.

The patient was seen again on August 1, 1947, at which time there was minimal evidence of callus formation around the subtrochanteric fracture of the left femur. Another follow-up roentgenogram on

Fig. 4. Case 4. a, Multiple myeloma with pathologic fracture of femur, June 20, 1947; b, after insertion of intramedullary nail, July 8, 1947.

October 14, 1947, showed considerable callus formation at the subtrochanteric fracture, but the fracture line itself was still clearly visible. The compounded injury of the right lower leg at that time revealed some drainage and roentgenograms showed no evidence of bony union. On December 2, 1947, a roentgenogram of the left femur showed callus formation over the medial aspect with evidence of healing at the fracture site. There was still absence of good bony healing of the right lower extremity. On March 8, 1948, a roentgenogram of the left femur showed union of the pathologic fracture of the femur, but the fracture line was still clearly visible over the lateral half of the shaft. Roentgenograms of the right lower extremity showed union of the fracture of the fibula and early bridging callus between the tibial fragments with a sequestrum at the tibial fracture site. The sequestrum was subsequently removed. At that time the patient had become ambulatory, using crutches for ambulation and bearing full weight on his left femur.

CASE 4. C. C., a 66-year-old woman, had been followed by the orthopedic service since January 1944, with the diagnosis of far advanced generalized rheumatoid arthritis. She showed evidence of generalized osteoporosis and also had a spondylolisthesis of the fourth lumbar vertebra on the fifth lumbar vertebra. She was admitted to the surgical service on June 20, 1947, stating that on the previous day while attempting to get out of a chair, the right thigh suddenly collapsed and she fell backward into the chair. She felt a pain in the region of her right hip and there was complete loss of use of her right lower extremity.

Examination of the patient on admission showed far advanced generalized rheumatoid arthritis with

Fig. 5. Case 5. a, Pathologic fracture of femur involved by Paget's disease, October 7 1947. b, after insertion of intramedullary nail, October 9 1947. c, 3 months after insertion of intramedullary nail, January 5 1948.

deformed joints and marked contracture deformities of the hands, feet, knees, elbows and spine. Inspection of the right lower extremity revealed swelling and valgus deformity just below the region of the hip and some internal rotation of the distal part of the femur and leg. Roentgenograms showed a transverse fracture in the upper half of the right femur below the lesser trochanter which had the appearance of a pathologic fracture. Roentgenograms of the patient's skull showed multiple rarefied areas of the skull bones.

On July 5 1947 under nitrous oxide and pentothal anesthesia, an open reduction and introduction of an intramedullary nail into the right femur was performed. The entire cortex of the femur was extremely osteoporotic and destroyed by a neoplastic process. The operative procedure was uneventful. Biopsy of tissue from the site of the fracture was taken which proved to be plasma cell type of multiple myeloma. The patient developed fever on the 2nd postoperative day but on the following day the temperature returned to normal levels. The remaining postoperative course was uneventful. The patient was quite comfortable and pain free as far as the fracture was concerned. She was discharged on the 14th postoperative day.

A follow up letter for information told of the patient's death on December 4 1947 six months after the pathologic fracture had occurred.

CASE 5 R.B. a 71 year old man was admitted to the surgical service on October 7 1947 with the complaint of a fractured left thigh of 1 week's duration. He stated that approximately 1 week before admission while slowly walking around a table he suddenly felt a snap in the region of his left hip which was followed by severe pain and loss of func-

tion of the left lower extremity. Roentgenograms taken in his local hospital revealed a fracture of the left femur. He was treated there by traction.

Examination on admission here showed a well developed and nourished man not in acute distress. His abdomen was somewhat distended and tympanic. There was marked external rotation of the left lower extremity below the level of the upper thigh. There was minimal ecchymosis about the region of the left hip anteriorly. Roentgenograms of the region of the left hip and left femur in anteroposterior and lateral views showed coarsening of the trabeculae of the bone with thickening of the cortex indicative of Paget's disease. There was a transverse fracture in the subtrochanteric region with shortening and posterior displacement of the distal fragment.

On October 9 1947 under nitrous oxide and pentothal anesthesia open reduction and insertion of a Kuntscher type nail was carried out. A biopsy of the bone at the fracture site showed sclerotic bone consistent with Paget's disease. The operative procedure was uneventful and the patient's postoperative course was afebrile. The patient reported immediate relief of pain at the fracture site. He was able to be up in a chair 2 days postoperatively and was able to raise his leg off the bed with ease and without limitation of motion at the hip or knee joints. He was discharged on the 13th postoperative day.

The patient was seen again on January 5 1948. The left lower extremity showed free motion of the hip and knee joints and there was no tenderness over the area of the fracture. Roentgenograms of the left femur showed marked callus formation around the fracture site and evidence of healing. The patient

Fig. 6. Case 6, a, Carcinoma of breast metastatic in femur June 6, 1944, b, fracture through area of metastatic bone involvement October 1, 1947, c, after insertion of intramedullary nail, October 6, 1947, d, 10 months after insertion of intramedullary nail, November 4, 1947.

returned again on April 9, 1948 at which time he was ambulatory and roentgenograms revealed the fracture to have healed.

Case 6 G.G. a 30 year old woman was first seen in this hospital on June 6, 1944 with the complaint of pain in her thigh and lower back of approximately 6 months duration. Physical examination showed a primary neoplastic mass in her right breast with axillary metastases. Roentgenograms showed metastasis to the lumbar spine, pelvis, upper end of the right femur and upper half of the left femur. Since that time the patient had received intensive irradiation therapy with considerable improvement enabling her to carry on her usual occupation.

The patient returned on October 11, 1947 stating that the left leg had spontaneously collapsed and she had fallen. On admission shortly after the accident, the patient appeared emaciated, pale and somewhat older than her stated age of 30. Over the upper portion of her right breast a hard fixed irregular mass was present and there were numerous hard fixed metastatic lymph nodes in the right axilla. Examination of the left lower extremity showed a fracture deformity of the thigh with point tenderness and local swelling. Roentgenograms showed a pathologic fracture of the upper third of the left femur through the known metastatic area involving the bone.

On October 13, 1948, under nitrous oxide and general anesthesia an open reduction was performed at the fracture site and a Kuentzner type nail was inserted. A biopsy taken from the neoplastic tissue at the fracture site showed a leiomyosarcoma in bone. The operative procedure was uneventful.

There was immediate relief of pain at the fracture site. Roentgenograms showed the nail in satisfactory position with good alignment of the fragments.

The patient's course in the hospital was complicated by a pathologic fracture through the right upper humerus which occurred on the 5th postoperative day while she was turning in bed. This fracture, however, was not displaced. The patient was able to move her left lower extremity freely and without pain following the operative procedure. She was placed on testosterone propionate therapy and discharged on the 17th postoperative day.

Follow-up roentgenograms on November 14, 1947 showed some evidence of healing of the pathologic fracture of the left femur.

The patient appeared at her home on February 7, 1948 four months after the introduction of the intramedullary nail.

Case 7 H.D., a 75 year old man was admitted to the surgical service January 20, 1948, complaining of a fractured right thigh of 1 week duration. He stated that for many years his right leg had been "weak" and he had suffered some discomfort in the thigh. About 1 week before admission while suddenly turning around, his right thigh buckled under him and he fell to the ground. There was considerable pain and swelling following this injury.

Physical examination on admission showed a 75 year old man who was obviously undernourished, dehydrated and somewhat disoriented. Examination of the right lower extremity showed a point of false motion at the junction of the upper and middle one-thirds of the femur with internal rotation of the

Fig. 7. Case 7. a, Pathologic fracture through femur involved by Paget's disease, January 29, 1948, b after insertion of intramedullary nail, February 4, 1948. c, 3 months after insertion of intramedullary nail, May 10, 1948.

distal portion of the leg. There was considerable soft tissue swelling around the site of fracture and some muscle spasm. Roentgenograms taken on admission showed a complete transverse fracture of the femur at the junction of the proximal and middle one thirds with posteromedial displacement of the distal fragment. The proximal femur including most of the intertrochanteric area and a portion of the femoral neck showed an over-all increase in width of the shaft, generalized thickening of the cortex and definite coarsening of the bony trabeculae. The bony changes were those of Paget's disease. These changes extended distally to include the fracture area, although the change there was not as striking as in the proximal portion of the femur. The impression was Paget's disease of the right femur with pathologic fracture at junction of proximal and middle thirds.

On January 30, 1948, open reduction at the fracture site and insertion of a Kuentscher type nail was performed under spinal anesthesia. Roentgenograms taken postoperatively showed the intramedullary nail in place with good approximation and alignment of the fragments. The patient's postoperative course was uneventful except for periods of disorientation. He was able to sit up in a chair on the 3rd postoperative day and was discharged from the hospital on the 17th postoperative day.

The patient returned for examination on May 10, 1948. Roentgenograms showed the fracture to have healed. There was full range of motion of the hip and knee joints and the patient was ambulatory.

CASE 8. E.B., a 76 year old woman had been seen in this hospital intermittently since June 1947 with the diagnosis of carcinoma of the left breast with widespread osseous metastases. She had inten-

sive treatment with testosterone propionate with remarkable relief of pain and regression of all bony lesions. She was admitted to the surgical service on February 18, 1948, stating that 2 days before admission while walking in her bathroom with the aid of

Fig. 8. Case 8. a, Pathologic fracture secondary to metastatic carcinoma of breast, February 18, 1948. b, after insertion of intramedullary nail, February 20, 1948.

Fig. 6. Case 6. a, Carcinoma of breast metastatic in femur, June 6, 1944; b, fracture through area of metastatic bone involvement, October 11, 1947; c, after insertion of intramedullary nail, October 6, 1947; d, 1 month after insertion of intramedullary nail, November 4, 1947.

returned again on April 9, 1948 at which time he was ambulatory and roentgenograms revealed the fracture to have healed.

CASE 6. G. G., a 30-year-old woman, was first seen in this hospital on June 6, 1944, with the complaint of pain in her thigh and a lump of approximately 6 months' duration. Physical examination revealed a primary neoplastic mass in her right breast with axillary metastasis. Roentgenograms showed metastases to the lumbar spine, pelvis, upper end of the right femur, and upper half of the left femur. Since that time the patient had received intensive irradiation therapy with considerable improvement enabling her to carry on her usual occupation.

The patient returned on October 11, 1947, stating that the left leg had spontaneously collapsed and she had fallen. On admission shortly after the accident the patient appeared emaciated, pale, and somewhat older than her stated age of 30. Over the upper portion of her right breast a hard, fixed, irregular mass was present and there were numerous hard, fixed metastatic lymph nodes in the right axilla. Examination of the left lower extremity showed a fracture deformity of the thigh with point tenderness and local swelling. Roentgenograms showed a pathologic fracture of the upper third of the left femur through the known metastatic area involving the bone.

On October 13, 1948, under nitrous oxide and pentothal anesthesia an open reduction was performed at the fracture site and a Kuntsche type nail was inserted. A biopsy taken from the neoplastic tissue at the fracture site showed adenocarcinoma in bone. The operative procedure was uneventful.

There was immediate relief of pain at the fracture site. Roentgenograms showed the nail in satisfactory position with good alignment of the fragments.

The patient's course in the hospital was complicated by a pathologic fracture through the right upper humerus which occurred on the 5th postoperative day while she was sitting in bed. This fracture, however, was not displaced. The patient was able to move her left lower extremity freely and without pain following the operative procedure. She was placed on testosterone propionate therapy and discharged on the 17th postoperative day.

Follow-up roentgenograms on November 14, 1947, showed some evidence of healing of the pathologic fracture of the left femur.

The patient expired at her home on February 7, 1948, four months after the introduction of the intramedullary nail.

CASE 7. I. L. D., a 75-year-old man, was admitted to the surgical service January 20, 1948, complaining of a fractured right thigh of 1 week's duration. He stated that for many years his right leg had been "weak" and he had suffered some discomfort in the thigh. About 1 week before admission while endeavoring to turn around, his right thigh buckled under him and he fell to the ground. There was considerable pain and swelling following this injury.

Physical examination on admission showed a 75-year-old man who was obviously undernourished, dehydrated, and somewhat disoriented. Examination of the right leg, which was extremely swollen, showed a point of flexion motion at the junction of the upper and middle one thirds of the femur, with internal rotation of the

Fig. 7. Case 7. a, Pathologic fracture through femur involved by Paget's disease, January 20, 1948, b, after insertion of intramedullary nail, February 4, 1948. c, 3 months after insertion of intramedullary nail, May 10, 1948.

distal portion of the leg. There was considerable soft tissue swelling around the site of fracture and some muscle spasm. Roentgenograms taken on admission showed a complete transverse fracture of the femur at the junction of the proximal and middle one-thirds with posteromedial displacement of the distal fragment. The proximal femur including most of the intertrochanteric area and a portion of the femoral neck showed an over-all increase in width of the shaft, generalized thickening of the cortex and definite coarsening of the bony trabeculae. The bony changes were those of Paget's disease. These changes extended distally to include the fracture area although the change there was not as striking as in the proximal portion of the femur. The impression was Paget's disease of the right femur with pathologic fracture at junction of proximal and middle thirds.

On January 30, 1948, open reduction at the fracture site and insertion of a Kuntscher type nail was performed under spinal anesthesia. Roentgenograms taken postoperatively showed the intramedullary nail in place with good approximation and alignment of the fragments. The patient's postoperative course was uneventful except for periods of disorientation. He was able to sit up in a chair on the 3rd postoperative day and was discharged from the hospital on the 17th postoperative day.

The patient returned for examination on May 10, 1948. Roentgenograms showed the fracture to have healed. There was full range of motion of the hip and knee joints and the patient was ambulatory.

CASE 8. E.B. a 76 year old woman had been seen in this hospital intermittently since June 1947 with the diagnosis of carcinoma of the left breast with widespread osseous metastases. She had inten-

sive treatment with testosterone propionate with remarkable relief of pain and regression of all bony lesions. She was admitted to the surgical service on February 18, 1948 stating that 2 days before admission while walking in her bathroom with the aid of

Fig. 8. Case 8. a, Pathologic fracture secondary to metastatic carcinoma of breast, February 18, 1948. b, after insertion of intramedullary nail, February 20, 1948.

Fig. 9. Case 9. a, Carcinoma of breast with pathologic fracture of femur of 3 months' duration, 31 Feb. '38, 948 b, after insertion of intramedullary nail, March 20, 1948.

Fig. 10. a, Pathologic fracture of femur metastatic hypernephroma, April 1948 b, after insertion of intramedullary nail, April 24, 1948.

a came her right leg suddenly buckled and she fell. Physical examination on admission showed an obese woman apparently not in acute distress. There was striking hirsutism of the face. Her voice was deep. The left breast was larger than the right. The nipple was retracted. There was orange-peel type of skin over the entire lower portion of the left breast, overlying a hard immobile nontender mass. Examination of the right lower extremity which was immobilized in Thomas splint traction showed some swelling and pain on pressure in the region of the mid-shaft of the femur. Roentgenograms of the pelvis and right femur revealed extensive neoplastic metastasis to the pelvis and femur with pathologic fracture of the right femur about 2 centimeters below the lesser trochanter.

On February 20, 1948, under nitrous oxide and pentothal anesthesia open reduction and insertion of an intramedullary nail was performed. A biopsy taken from the tissue at the fracture showed poorly differentiated metastatic carcinoma in bone. The patient's postoperative course was quite uneventful. Roentgenograms postoperatively showed the fragments of the pathologic fracture of the femur to be in excellent position and alignment. The relief of pain was remarkable. The patient was discharged from the hospital on the 13th postoperative day.

CASE 9. G.R., a 67 year old woman was first admitted to the surgical service on June 17, 1946, with the diagnosis of carcinoma of the left breast and axillary metastasis. A radical mastectomy was performed. During October, 1946 she developed severe pain in the upper right thigh. Roentgenograms at that time revealed an early destructive lesion in the

upper right femur approximately 3 inches below the lesser trochanter. The patient was treated with testosterone propionate but there was continued progression of the lesion. On October 18, 1947 the patient suffered a pathologic fracture through the involved area. Roentgenograms at that time showed a transverse fracture through the middle of a metastatic area in the upper one third of the right femur. The patient was placed in a hip spica cast. Many follow-up roentgenograms failed to show any callus formation or healing of the pathologic fracture.

The patient spent 5 months in a cast until March 20, 1948, at which time diamond shaped Hanes Street¹ intramedullary nail was inserted and an open reduction was done at the fracture site. The operative procedure was carried out under nitrous oxide and pentothal anesthesia. A biopsy taken from the area of involvement showed poorly differentiated adenocarcinoma in scar tissue. The postoperative course was quite uneventful and the patient was able to move her leg within a few days following the operation and was able to get up into a chair. She was completely free of pain and was discharged from the hospital on the 16th postoperative day.

CASE 10. J.H., a 65 year old man was admitted to the hospital on April 21, 1948. He stated that he had been perfectly well until about 6 weeks before admission, at which time he noticed some pain in the right thigh and leg. This pain increased in severity but he was able to walk and pursue his usual activity. On April 20, 1948 while walking on his porch, his right leg suddenly buckled under him and he fell. Roentgenograms at the local hospital revealed a fracture through the upper portion of the right femur.

Physical examination on admission showed a well developed and well nourished white male not appearing acutely ill. Heart and lungs were normal to percussion and auscultation. No abdominal masses could be felt. Inspection of the right lower extremity which was immobilized in a Thomas splint at the time of admission showed some angulation and swelling in the upper portion of the thigh. Roentgenograms revealed a transverse fracture through the subtrochanteric region of the right femur the fracture line running through an area of decreased density representing an osteolytic metastatic lesion. Other osteolytic metastatic lesions were seen in the tuberosity of the right ischium, in the right ilium and in the left parietal region of the skull.

On April 23, 1948 an open reduction was performed and an intramedullary nail of the Hansen Street type was inserted into the right femur under spinal anesthesia. A biopsy was taken during the time of the open reduction. Sections from this biopsy showed metastatic hypernephroma. The operative procedure was uneventful and the patient's postoperative course was afebrile. He was able to lift his leg without undue pain on the 2nd day following the surgical procedure. He was up in a chair 48 hours after the intramedullary nail had been inserted. Postoperative roentgenograms showed the intramedullary nail in place with excellent alignment of the fragments at the site of fracture. Retrograde and intravenous pyelograms showed the primary neoplasm to be in the left kidney. The patient was permitted to walk with the aid of crutches on the 5th postoperative day. He was discharged on the 10th day, completely pain free and ambulatory with the aid of crutches.

DISCUSSION

We have reported 10 cases of pathologic fracture of the femur treated by fixation with an intramedullary nail. Of the fractures reported 4 were due to Paget's disease, 5 to metastatic carcinoma, and 1 to multiple myeloma. There is no evidence from this small series that dissemination of the tumor was hastened in the patients with metastatic carcinoma or that the terminal course of the disease was unfavorably influenced. In the 4 cases of Paget's disease a solid union occurred within a period of approximately 4 months.

In each instance immediate relief of pain at the fracture site was striking. No patient required external immobilization. All patients were placed upon a Boehler frame for a few days to effect elevation and temporary immobilization of the extremity. In no instance was the postoperative course complicated by wound infection, shock, hemorrhage or fat embolism. Special nursing care of the type re-

quired for conventional skeletal traction or cast cases was not necessary. The average period of hospitalization following introduction of the nail was only 2 weeks. Because of slight bending of the tubular type nail in 2 instances (one in this series and another in fixation of a simple fracture) we have abandoned the use of this type nail and have substituted the solid diamond shaped Hansen Street nail for femoral fractures (8).

In our experience healing is facilitated by this method not only under the abnormal conditions of pathologic fracture but is aided also in other fractures where unusual conditions are present such as those imposed by poor general condition of the patient and unfavorable local conditions (e.g. long standing non union with sclerosis of the medullary cavity). We have found that a number of such fractures have healed when ordinarily one would not have anticipated such a result. Where nonunion has occurred we have been able to use the intramedullary nail in conjunction with on lay bone grafts with early healing and satisfactory function of the extremity (9).

SUMMARY

This is a report of 10 cases of pathologic fracture of the shaft of the femur, 4 of which were due to Paget's disease, 5 to metastatic carcinoma, and 1 to multiple myeloma, which were treated by intramedullary nailing.

The intramedullary nail fixation was followed by early relief of pain, free mobility of the extremity, reduction in the amount of nursing care, and a decreased period of hospitalization.

In the cases of Paget's disease early healing was effected and early ambulation attained.

PROLONGED SPINAL ANESTHESIA USE OF INTRATHECAL VASOCONSTRICTOR SUBSTANCES

M. LAWRENCE BROCKMYER, M.D. and THORBURN S. MCGOWAN, M.A. M.D. F.A.C.S.
Seattle, Washington

THE many advantages of spinal anesthesia for all surgery below the diaphragm and including the lower extremities are well known and widely accepted. In the past, the chief disadvantage has been the unpredictable time element. Despite its obvious advantage to the surgeon in particular complete muscular relaxation the short and uncertain duration of anesthesia has prevented its wider acceptance. The purpose of this paper will be to demonstrate a means whereby with reasonable certainty and safety anesthesia with complete muscular relaxation can be obtained and maintained even in the upper abdomen for periods averaging over 3½ hours with a single intrathecal installation.

There have been many attempts in the past to prolong spinal anesthesia. These developments have resolved themselves into three approaches, namely (1) the use of different anesthetic agents or combinations of them (2) the use of repeated injections of the same agent (fractional spinal anesthesia) (3) the use of vasoconstrictor drugs intrathecally.

In 1898 August Bier of Bonn Germany who is recognized as the real father of spinal anesthesia, used, or rather had used on himself the first spinal anesthetic: 2 cubic centimeters of 1 per cent solution of cocaine (20 mgm) was injected into his subarachnoid space by an assistant. Satisfactory anesthesia was reported with a mild headache as the only sequela. Rudolph Matas published the first account of the use of a spinal anesthetic in the United States. In 1904 Fournieu introduced stovaine and Babcock popularized its use in this country. Procaine (novocain) was introduced by Einhorn in 1905. In 1907 the gravity control method was described independently by Barker and Chaput. In recent years pro-

caine (novocain) dibucaine (nupercaine) tetracaine (pontocaine) and piperocaine (L.A. 33 or metycaine) have been the potent substances most generally used. Procaine has, in the therapeutic doses usually used, produced satisfactory anesthesia with a minimum of toxic effect but in most hands, as in ours, its action has been of short duration. Metycaine and pontocaine, although longer acting have generally proved somewhat more toxic in the amounts usually employed. Nupercaine, although the longest acting is among the most toxic and even in competent hands has occasionally given rise to serious and fatal complications.

Many combinations of the various anesthetic agents have been tried and reports in the literature imply that there has been definite prolongation. Romberger in 1931 stated that a mixture of 5 to 7½ milligrams of nupercaine with 150 to 200 milligrams of procaine would give an anesthesia lasting from 2½ to 3 hours. Lewis in 1944, reporting on 300 cases, showed the average duration of such an anesthetic to be 113 minutes. His longest recorded time interval for anesthesia was 3 hours and 5 minutes, by using 3 to 8 milligrams of nupercaine with 50 to 100 milligrams of procaine.

The work of Lemmon on fractional spinal anesthesia published in 1940 immediately opened a new vista. At last the time element could be so regulated that the surgeon could complete prolonged operations and close abdominal incisions under perfect muscular relaxation with the bowel still collapsed. With the fractional method the anesthetic agent could be administered in divided smaller dosage with significant reduction in toxicity. This was found to be of particular importance in poor risk patients.

Unfortunately however the use of fractional spinal anesthesia whether by malleable needle or indwelling catheter is not a simple

From the Surgical Service, U. S. Marine Hospital, Seattle, Washington.

procedure. It calls for more complex equipment. In addition a special table surface is required unless a catheter is introduced into the subarachnoid space. This is uncertain at best and often difficult. In clinics and hospitals with large and expertly trained staffs specializing in anesthesia this method can be depended on to produce satisfactory anesthesia in approximately 90 per cent of cases attempted but its complexities are such that it is rarely used in the smaller hospitals or clinics and certainly not in those situations in which the surgeon must of necessity give the anesthetic and then depend upon relatively untrained personnel to administer further doses at appropriate times.

While general attention has not been attracted to the use of intrathecal vasoconstrictor agents as a means of prolonging spinal anesthesia until very recently this is not a new procedure. In 1905 Heineke and Lawen reported the use of novocain adrenalin solution without ill effect. In 1911 Richards reported the use of suprarenin borate with procaine and normal saline solution. In 1943 Romberger quoted Hertzler as stating in an extemporaneous speech in 1934 that he had used intraspinal epinephrine for a good many years to prolong the effect of the anesthetic. Romberger in recalling his techniques in administering spinal anesthetics stated that in 108 cases he had used $\frac{1}{2}$ to $\frac{3}{4}$ cubic centimeter of a 5 per cent ephedrine solution and obtained 40 to 50 per cent longer duration of anesthesia. In 131 cases in which he used a 1:40,000 up to 1:120,000 dilution of adrenalin he reduced the amount of procaine necessary 25 per cent and prolonged the anesthesia from 100 to 150 per cent. One patient had motor relaxation for $2\frac{1}{2}$ hours and sensory anesthesia for $3\frac{1}{4}$ hours. Pitkin in 1939 advocated the use of a nonoxidizing epinephrine with subarachnoid capacity control. With this new solution plus 300 milligrams of novocain he reported anesthesia in the upper abdomen for 2 to $2\frac{1}{2}$ hours and with 200 milligrams of novocain anesthesia in the lower abdomen for 3 hours. When pontocaine was used similarly, 20 milligrams produced anesthesia in the upper abdomen for $2\frac{1}{2}$ to 3 hours, in the lower abdomen 4 to 5 hours and in the perineal region 5

hours. Prickett, Cullen and Gross in 1945 reported 108 cases in which they used procaine and epinephrine in dilutions of 1:30,000 and 1:100,000 with a definite prolongation of the anesthesia. Shane and Ruiz in 1945 reported 200 cases in which pontocaine-glucose solutions containing 0.2 cubic centimeter of 1:1,000 epinephrine prolonged anesthesia with less anesthetic agent required. They stated that other vasoconstrictors (methedrine, neosynephrine and ephedrine) were used, but did not prove as effectual as epinephrine.

Whitacre and Potter in 1948 reported the use of epinephrine or ephedrine both with pontocaine or nupercaine intrathecally. The anesthetic effect of pontocaine and dextrose was not altered by the addition of epinephrine but with ephedrine there was a 20 per cent increase in duration with a concomitant 30 per cent decrease in the amount of the drug necessary to produce comparable anesthesia. Conversely a hypobaric nupercaine-epinephrine solution produced an increased anesthetic effect but a hypobaric nupercaine-ephedrine solution did not give significant results. From the foregoing it can be seen that many contradictory and conflicting claims have been made in the distant and recent past.

Continuous spinal anesthesia was introduced in this hospital in 1945 by one of the authors nevertheless in spite of careful adherence to detail an appreciable number of patients still occasionally failed to get and often to maintain a high and adequate anesthesia. Unfortunately also more than twice as much time was needed to administer the initial anesthetic dose by this method than by the so-called 'one shot spinal'. In an effort to obtain the same advantages inherent in the fractional spinal anesthetic and at the same time to abolish its complexities and uncertainties one of the authors began the intrathecal use of epinephrine and ephedrine in 1946 with fairly good results. At that time however it was felt that some other agent with more uniform action was desired and that after investigation of its physiologic and pharmacologic characteristics phenylephrine hydrochloride neosynephrin should be given a trial. It was used several times intrathecally in 10 milligram amounts with satisfactory results.

PROLONGED SPINAL ANESTHESIA USE OF INTRATHECAL VASOCONSTRICTOR SUBSTANCES

M LAWRENCE BROCKMYER, M.D., and THORBURN S McGOWAN M.A., M.D. F.A.C.S.,
Seattle, Washington

THE many advantages of spinal anesthesia for all surgery below the diaphragm and including the lower extremities are well known and widely accepted. In the past, the chief disadvantage has been the unpredictable time element. Despite its obvious advantage to the surgeon in particular complete muscular relaxation the short and uncertain duration of anesthesia has prevented its wider acceptance. The purpose of this paper will be to demonstrate a means whereby with reasonable certainty and safety anesthesia with complete muscular relaxation can be obtained and maintained, even in the upper abdomen for periods averaging over $3\frac{1}{2}$ hours with a single intrathecal installation.

There have been many attempts in the past to prolong spinal anesthesia. These developments have resolved themselves into three approaches namely (1) the use of different anesthetic agents or combinations of them (2) the use of repeated injections of the same agent (fractional spinal anesthesia) (3) the use of vasoconstrictor drugs intrathecally.

In 1898 August Bier of Bonn Germany who is recognized as the real father of spinal anesthesia, used or rather had used on him self the first spinal anesthetic 2 cubic centimeters of 1 per cent solution of cocaine (20 mgm) was injected into his subarachnoid space by an assistant. Satisfactory anesthesia was reported with a mild headache as the only sequela. Rudolph Matas published the first account of the use of a spinal anesthetic in the United States. In 1904 Fournneau introduced stavaine and Babcock popularized its use in this country. Procaine (novocain) was introduced by Einhorn in 1905. In 1907 the gravity control method was described independently by Barker and Chaput. In recent years pro-

caine (novocain) dibucaine (nupercaine) tetracaine (pontocaine) and piperocaine (L A 33 or metycaine) have been the potent substances most generally used. Procaine has, in the therapeutic doses usually used, produced satisfactory anesthesia with a minimum of toxic effect but in most hands, as in ours, its action has been of short duration. Metycaine and pontocaine, although longer acting have generally proved somewhat more toxic in the amounts usually employed. Nupercaine, although the longest acting is among the most toxic and even in competent hands has occasionally given rise to serious and fatal complications.

Many combinations of the various anesthetic agents have been tried and reports in the literature imply that there has been definite prolongation. Romberger in 1931 stated that a mixture of 5 to $7\frac{1}{2}$ milligrams of nupercaine with 150 to 200 milligrams of procaine would give an anesthesia lasting from $2\frac{1}{2}$ to 3 hours. Lewis in 1944 reporting on 300 cases, showed the average duration of such an anesthetic to be 112 minutes. His longest recorded time interval for anesthesia was 3 hours and 5 minutes, by using 3 to 8 milligrams of nupercaine with 50 to 100 milligrams of procaine.

The work of Lemmon on fractional spinal anesthesia published in 1940 immediately opened a new vista. At last the time element could be so regulated that the surgeon could complete prolonged operations and close abdominal incisions under perfect muscular relaxation with the bowel still collapsed. With the fractional method the anesthetic agent could be administered in divided smaller dosage with significant reduction in toxicity. This was found to be of particular importance in poor risk patients.

Unfortunately however the use of fractional spinal anesthesia whether by malleable needle or indwelling catheter is not a simple

From the Surgical Service, U. S. Marine Hospital, Seattle Washington

checked until the desired level is reached. This level is initially determined by pinching the patient's skin at the shoulder level and then starting similar pinches on the thigh and moving upward until the pinprick is as sharp as at the shoulder level. This is repeated on the opposite side and the sides checked continually watching the level rise to the desired dermatome after which the table is leveled off from its former Trendelenburg position. Only now may the acute flexion of the neck be dropped. It should be emphasized that to obtain the proper anesthetic level with good muscular relaxation the pinpricks should delineate the anesthetic, not the hypesthetic zone which is a spread or diffusion effect of approximately one dermatome breadth. The sharply flexed neck has in every instance prevented a rise in anesthesia beyond the 1st to 2nd thoracic segment. In our hands there has been no further extension of anesthesia after the initial 10 to 12 minutes either adventitiously or on the deliberate attempt of the surgical staff. This fixation has not been affected by the use of neosynephrin and points to its possible mode of action namely delaying the removal and/or oxidation of the anesthetic agent from the nerve roots. This is accomplished by limiting the access and egress of blood to and from this area rather than by delaying absorption of the anesthetic drug by the nerve root. Accordingly once fixed there is no contraindication to the Trendelenburg or reverse Trendelenburg positions.

The level usually obtained for upper abdominal surgery is the 3rd thoracic segment, the 5th thoracic for lower abdominal surgery, the 6th thoracic for hernioplasty and 7th to 8th thoracic for lower extremity and proctologic-perineal surgery. A graphic dermatome chart is maintained in the anesthesia book to be constantly available for reference. A most helpful maneuver is to ask the patient to raise his head and neck. If the upper recti fail to contract, the level of the anesthesia is above the 6th thoracic and abdominal surgery can be done without pain and with good muscular relaxation.

Anesthetist The deliberate use of 12 members of the surgical staff and 12 interns as anesthetists excludes the single expert anesthetist

from consideration as a factor influencing the results.

Amount of vasoconstrictor agent To control this study properly it was decided to apply the vasoconstrictor agent in both single injection and continuous spinal anesthesia. Both the type of drug and the amount of the anesthetic agent were allotted for various regions, as follows

	Mgm	
Rectal and perineal	50-100	Procaine
Hernioplasty unilateral	8	Pontocaine
Hernioplasty bilateral	10	Pontocaine
Lower extremity	10	Pontocaine
Lower abdominal	10	Pontocaine
Upper abdominal	12	Pontocaine

Since it was determined by the workers at the University of Utah that an optimum amount of neosynephrin was reached after which any further increase added nothing to the prolongation effect, and that this point was found to be approximately 5 milligrams it was arbitrarily decided to use 3 milligram amounts throughout this study in every instance. The pontocaine-glucose neosynephrin solutions are thoroughly mixed together in the syringe prior to injection.

Continuous spinal anesthesia This has been the choice for gastric resections and other similar procedures in which the time factor is in doubt at the start of the operation. It is also used in spinal fusions. The following formula has been adhered to

	Gastric resection	Spinal fusion
Glucose	4 c.c.	3 c.c.
Pontocaine	4 c.c. (60 mgm.)	4 c.c. (40 mgm.)
Neosynephrin	1½ c.c. (15 mgm.)	1 c.c. (10 mgm.)
Spinal fluid	8½ c.c.	5 3 c.c.
	20 c.c.	13 3 c.c.

Initially 4 cubic centimeters of this solution which contains 3 milligrams of pontocaine per cubic centimeter or a total of 12 milligrams of pontocaine and 3 milligrams of neosynephrin is injected after the patient has been placed in a 30 to 40 degree Trendelenburg position with the neck acutely flexed.

Sectional hinged raised plywood forms have been devised at this hospital and are interchangeably fixed to the operating table tops so that an aperture exists over the area in the lumbar spine from which the malleable needle

About this time Dr. R. G. Lewis, one of the newly arrived interns, related the prior experiences of Dr. Scott M. Smith at the University of Utah Medical School in the use of neosynephrin intrathecally. Dr. Lewis was associated in some of the preliminary investigative work under Dr. Smith, and after learning about their preliminary conclusions it was decided that a statistical study on the use of neosynephrin intrathecally was indicated at this hospital with particular attention to any disadvantages which might contraindicate its more extensive use.

NEOSYNEPHRIN

The formula of neosynephrin hydrochloride

Its physiologic action has been shown by Keys and Violante to produce a rise in blood pressure and a fall in pulse rate when used in 3 to 10 milligram doses subcutaneously. The blood pressure rise is due to its adrenergic effect which causes a peripheral vasoconstriction with simultaneous coronary dilatation and increased cardiac output. The most probable cause of the bradycardia is reflex stimulation of the vagus nerve occurring as a result of the elevated blood pressure. In comparing it with epinephrine and ephedrine Johnson found it superior because its effect was of longer duration, no extrasystoles or abnormal rhythms were produced and it had a much wider margin of safety. The lethal intravenous dose in dogs being 150 milligrams as contrasted with 70 to 75 milligrams for ephedrine and 0.1 to 0.6 milligrams per kilogram weight for epinephrine. From these physiologic considerations neosynephrin was believed to be the vasoconstrictor agent of choice.

TECHNIQUE

A rigid technique for spinal anesthesia already had been evolved for use at the Seattle Marine Hospital and in the past adherence to it had produced uniformly controlled levels of anesthesia. Throughout this study adherence to this technique has been meticulous and must be followed in detail to duplicate these

results. All patients for spinal anesthesia receive a barbiturate $\frac{1}{2}$ hour before operation. Morphine and scopolamine are given subcutaneously 30 minutes prior to surgery. All patients receive 50 milligrams of ephedrine sulfate intramuscularly as soon as the skin wheal has been raised and before the spinal needle is introduced. A Pitkin type needle, usually 22 gauge, is used.

Site of injection. The site depends on the region involved in the operation. With the patient in the lateral recumbent position the 1st or 2nd lumbar interspace is used for upper abdominal operations, the 3rd lumbar interspace for lower abdominal operations and hernioplasties, and the 4th lumbar interspace for rectal and lower extremity operations.

Method of injection. With pontocaine no spinal fluid is removed. With procaine 2 cubic centimeters of spinal fluid is removed and mixed with the procaine crystals. 10 per cent glucose is added in 1 cubic centimeter quantities to the anesthetic mixture for lower abdominal, 2 cubic centimeters to the mixture for upper abdominal surgery. The hyperbaric system is used exclusively here. (In no institution should there be concurrent use of both hypobaric and hyperbaric systems, as eventually tragic results will always follow.) To obtain a uniform potent concentration of the anesthetic agent at the higher dermatome levels the solution must be sufficiently heavier than spinal fluid that gravity will quickly carry it to the desired point before too great diffusion occurs. The well mixed solution is administered in the upper lumbar interspaces with the needle bevel directed cephalad, and is injected as quickly as is feasible with no barbotage following. This has enabled the rapid establishment of constant high and definite levels of anesthesia.

Position after injection. Immediately after injection the patient is turned on his back and the table dropped sharply into 30 to 40 degree Trendelenburg position with haste. The neck in extreme flexion supported on one folded or two flat pillows. Shoulder braces are essential to prevent slipping of the patient.

Height of anesthesia. Immediately upon placing the supine patient in the Trendelenburg position reaction to pinprick is bilaterally

orthopedic procedures from spinal fusion and hemipelvectomy to open and closed reduction of fractures are covered. All the usual proctologic conditions are included.

Experimental results The one best criterion for any anesthetic is abolition of pain and maintenance of complete muscular relaxation for the duration of surgery. Based on this criterion in 1 000 cases excluding 1 per cent failures satisfactory anesthesia was maintained for the duration of surgery as indicated in Table I.

These figures represent only the time from establishment of anesthesia to the close of surgery and do not necessarily indicate the total duration of anesthesia. Actually when investigated as outlined on the basis of (1) appearance of pain at the site of incision (2) ability to move legs again, and (3) pain to pinprick at the dermatome level of the skin incision, the duration of anesthesia is much longer. Since the recorded average duration is so prolonged that it started even the authors no case was included in determining the final averages unless all its data had been completely recorded. This was true in the 655 cases divided by region and showing the average duration of anesthesia as represented in Table II.

Since this long duration of anesthesia was achieved with less than half the regularly accepted dosages of the anesthetic drugs, it was decided to analyze these cases by amount of drug used to discover the effect, if any, of increased dosage to the duration of anesthesia. The analysis bears out the clinical impression that as the amount of the anesthetic agent is increased the duration of anesthesia is extended.

COMPLICATIONS AND DISADVANTAGES

These results were recorded in the entire series of 1 000 cases. In every instance, except 10 satisfactory anesthesia was obtained a failure index of 1 per cent. In 6 of these the blood pressure rose sharply immediately following injection indicating a systemic effect from the vasoconstrictor substances. These patients usually complained of headache. This obviously represents absorption of the neosynephrin into the general circulation and

TABLE I—AVERAGE OPERATING TIME

Region	No. cases	Drug	Amount mgm.	Average time hr. min.
Rectal and perineal	114	Procaine	50-100	43

Continuous spinal	96	Pontocaine	19 g	4 08
Total	1,000	(average)		

conversely indicates that the anesthetic solution was not deposited intrathecally. No completely satisfactory explanation could be given for failure in the other 4 cases. In every instance a supplemental tap was done clear spinal fluid withdrawn and sent to the laboratory for qualitative and quantitative determination of the anesthetic drug which was present in each instance and in quantities deemed adequate for anesthesia. In 1 of these cases local and regional infiltration with 1 per cent procaine hydrochloride was executed without anesthesia resulting even in the skin wheals. This robust individual required massive doses of pentothal in more than double the amounts usual for similar procedures.

Supplemental measures, usually toward the end of surgery were necessary in 56 cases or 5.6 per cent of the total. Intravenous morphine was used in 33 cases, pentothal in 17, cyclopropane in 3, nitrous oxide-pentothal in 1, and local infiltration with procaine in 2.

The disadvantage of nausea was present in 51 cases or 5.1 per cent. A considerable number of these patients experienced a fall in systolic blood pressure in the first 10 minutes following administration of the anesthetic. 100 per cent oxygen inhalations relieved this group in every instance. In a smaller per-

TABLE II.—DURATION OF ANESTHESIA FROM CLINICAL CRITERIA

Type of operation	No. cases	Pain appears operative site		Able to move legs		Painful pinprick same dermatome	
		hr.	Min.	hr.	Min.	hr.	Min.
Rectal	86	3	40	2	37	3	18

head protrudes. This permits leading the special tubing to the side and thence to the head of the table where the anesthetist controls the syringe with the prepared solution. The lumbar tap is done from the lateral recumbent position the spinal fluid obtained mixed with the various agents, and with the patient supine in Trendelenburg position the solution is injected rapidly. The table is leveled to a 5 degree Trendelenburg and there maintained throughout the operation. Further fractional injections are given by the anesthetist so as to maintain muscular relaxation and permit surgery without discomfort to the patient. In every instance a light pentothal overlay is begun 2 hours after initial anesthesia to allay anxiety and provide physiologic rest for the remainder of the procedure. Surgical anesthesia has never been attempted with this drug and the amounts required throughout surgery are usually less than 1 gram.

STATISTICAL ANALYSIS

This study covers a series of 1,000 consecutive cases in which spinal anesthetics were used during the period from May 1947 through May 1948. The initial and most important criterion has been the maintenance of satisfactory anesthesia for the entire duration of surgery. In addition to maintenance of satisfactory anesthesia throughout the operation three additional points were selected in an attempt to establish further clinical criteria by which the duration of anesthesia could be assessed. The first of these criteria is the appearance of pain at the operative site. This definitely fixes the time that sensation returns to that dermatome level which includes the skin incision. Localization is more accurate in this hospital because transverse and oblique incisions are used exclusively. As the most reliable index of motor function (end of muscular relaxation) the ability to move both legs was chosen as the second criterion. To cross check on return of sensation and eliminate subjective factors, pain on pinprick at the dermatome level of the skin incision was introduced as the third criterion. These criteria were recorded by the interns and nurses on the various wards following the return of the patient from surgery.

Blood pressure and pulse rates were also determined prior to anesthesia and every 10 minutes for the first 30 minutes of anesthesia and again at the conclusion of the operation. Height of anesthesia was accurately determined in every instance by pinprick as already outlined and this level was recorded. A record was likewise made of the site of spinal puncture. The time of administration of the anesthetic, the time surgery was initiated and concluded were also recorded in every instance.

In a previous series in which over 2,000 spinal anesthetics were administered at the Seattle Marine Hospital and in which intrathecal vasoconstrictors were not used, the average duration of anesthesia was found to range from 100 minutes with 16 to 20 milligrams of pontocaine in the upper abdomen 70 minutes in the lower abdomen and inguinal area for 150 milligrams of procaine, to 55 minutes in the perineal area for 50 to 100 milligrams of procaine.

Maxon in this book *Spinal Anesthesia* lists the average duration of anesthesia for the usual dosage of procaine as 60 minutes, pontocaine as 90 to 120 minutes, and nupercaine as 2 to 4 hours. The duration of spinal anesthesia varies considerably with the individual case this despite rigid adherence to an identical technique in the hands of the same anesthetist. Maxon reports a spread from 55 to 90 minutes under identical circumstances. Vehr reported variation from 12 minutes to more than 2 hours.

DIVERSITY OF SURGICAL MANEUVERS

The present series of 1,000 consecutive cases in which neosynephrin has been used intrathecally as a vasoconstrictor agent has been subdivided into the five categories already mentioned. In the upper abdomen all the common procedures and the more formidable such as total pancreatectomy are included with over 50 gastric resections in this group. In the middle and lower abdomen the range is from appendectomy to colectomy. The entire range of gynecologic and urologic surgery is represented. Five cesarean sections are included in obstetrics. Over 200 assorted hernias are included. Many difficult

cent of the series. The routine use of an indwelling catheter in the early postoperative period is practiced in bladder and prostatic surgery, abdominoperineal resection, vesicovaginoplasty and rectovaginoplasty, and also in panhysterectomy.

COMMENT

The authors do not offer their three additional criteria as proof that satisfactory surgical anesthesia will persist for this entire time and believe instead that the average safe interval for surgery lies approximately halfway between the average time in surgery and that recorded by these additional criteria. As such 3 to 3½ hours of surgical anesthesia can reasonably be expected for surgery of the upper abdomen from 12 milligrams of pontocaine combined with 3 milligrams of neosynephrin. This represents more than 100 per cent prolongation of anesthesia with a 50 per cent simultaneous reduction in the amount of drug used. Comparable results follow for the other regions. This should allow the average surgeon to use a single injection of a spinal anesthetic with a feeling of confidence in the duration of anesthesia and freedom from undesirable sequelae. Some individual variations can be expected in a small percentage of cases but such patients should usually respond to simple supplemental measures.

The unusually close average correlation of the two methods of determination of sensory return has been noted with interest. The slightly more rapid return of motor function was expected and proved true except in fractional spinal anesthesia where there was a uniform unexplained delay in its return.

In general it appears that to produce adequate high anesthesia, larger amounts of the potent drug must be introduced closer to the desired site of action (through a higher site of injection) and with a proportionally heavier solution. When this is done however a longer overall period of anesthesia results.

To the patient the 10 to 1 per cent of postpuncture headaches is the only disagreeable complication. Since at present the cause of 'postpuncture headache' is not understood,

it will be difficult to correct this factor but further studies on the relation of headache to the use of the glucose weighing vehicle are now in progress. In time these will be reported in an effort to arrive at the ideal combination of agents to prolong spinal anesthesia with a single injection.

CONCLUSIONS

1 This paper presents the technique used at the Seattle Marine Hospital in the administration of spinal anesthesia. It is used in all surgery below the diaphragm, the usual contraindications excepted.

2 A brief review of the literature of the various methods used by other workers in their attempts to prolong spinal anesthesia has been included.

3 The results over a 12 month period in 1,000 consecutive cases have been described.

4 No fatalities or permanent sequelae ensued.

5 Neosynephrin in 3 milligram doses when added intrathecally to the anesthetic agent safely prolongs the duration of spinal anesthesia over 100 per cent with a significant reduction in the amount of anesthetic agent required.

6 Three to 3½ hours of satisfactory surgical anesthesia in the upper abdomen can be achieved from a single injection of spinal anesthetic in over 90 per cent of all cases.

7 In continuous spinal anesthesia neosynephrin reduces the frequency of subsequent injections as well as the total amount of anesthetic agent necessary. This is of particular importance in poor risk patients.

8 The complications and disadvantages have been of extremely low incidence and have been discussed with an attempt to explain the reasons for their occurrence and precautions to be taken to avoid them in the future.

9 This method of anesthesia can be administered satisfactorily by the average surgeon. This should be of particular value to those surgeons who practice in the smaller hospitals.

10 Further investigation is in order to discover the ideal vasoconstrictor agent, anesthetic agent, and combination thereof whereby

centage of the group nausea was evidenced when tension was made on the abdominal esophagus and disappeared when tension was released.

A drop in systolic blood pressure greater than 10 milligrams of mercury occurred in 92 cases (92%) in the first 10 minutes following administration of the anesthetic. In 3 instances ephedrine had not been administered subcutaneously and in this and 5 other instances 3 milligrams of neosynephrin was given for its systemic effect. In no other instance was any supplemental vasopressor drug used. It was most interesting to note that in approximately 75 per cent of the entire series the blood pressure level 30 minutes following anesthesia was significantly higher than that prior to anesthesia. It must be remembered that 50 milligrams of ephedrine was used uniformly at the time anesthesia was administered.

In this series there were no fatalities or neurologic complications. There were 4 instances of high spinal anesthesia indicating medullary involvement 1 of which was severe. This person was so heavily sedated that co-operation was difficult. It is believed that positioning following administration of the anesthetic mixture accounted for its subsequent level. Since his spine was to be explored for a lumbar disc herniation he was left in the lateral decubitus position the table dropped to 35 degree Trendelenburg and the neck flexed upward laterally. Actually the upward curve of the neck produced in the lateral projection was insufficient to stop the progression of the hyperbaric solution. Respiration and heart action were temporarily paralyzed. By bag resuscitation with an adequate airway compression bandaging of all extremities, the prompt removal of 60 cubic centimeters of spinal fluid, and forced rapid infusion of plasma and dextrose to restore blood volume the vital functions returned and the anesthetic level gradually receded. His subsequent recovery was complete. The other 3 persons responded immediately to less drastic measures. From that time on it has been the rule that all anesthesia levels rectal and perineal cases excepted are to be established with the patient in the supine

position and only after fixation shall other positioning be done.

No serious or permanent sequelae resulted. Headache was the most common, almost the only complaint due to anesthesia recorded in the postoperative course and was noted in 101 cases or 10.1 per cent. It must be borne in mind, however that the surgical staff and nurses were alerted to its possible occurrence and instructed to record every instance in a special book. Symptoms were typical of the 'postpuncture type with onset usually the second postoperative day inaugurated and aggravated by the erect position and relieved by recumbency. They ranged from mild to severe, most of them mild of 1 to 2 days' duration and not very troublesome. There were several however that lasted 7 to 10 days necessitating intravenous caffeine sodium benzoate and occasionally ergotamine tartrate intramuscularly. In this group there were 2 patients who complained of stiffness of the neck and evidenced nuchal rigidity indicative of meningismus of a mild and transitory nature. No specific treatment was required. It should be remembered that early ambulation (the first postoperative day in all cases) is maintained. This may have resulted in more headaches being noted than in institutions where recumbency is enforced.

Early ambulation however together with deep breathing exercises and frequent changes in position beginning immediately upon the return of the anesthetized patient to the ward, is in the opinion of the authors responsible for the unusually negligible incidence of pulmonary complications. In this entire series there were only 2 cases of massive atelectasis, both recognized and bronchoscoped the night of operation. Their recoveries were uneventful thereafter. There was only 1 instance of 'postoperative pneumonia. There were no cases of fatal pulmonary infarction. Infarction of minor degree was recognized in 9 cases.

Contrary to popular opinion and quite likely influenced profoundly by early ambulation catheterization was performed in only 33 cases including the urological cases. In only 1 case was it necessary more than once. Male patients comprise approximately 93 per

cent of the series. The routine use of an indwelling catheter in the early postoperative period is practiced in bladder and prostatic surgery, abdominoperineal resection, vesicovaginoplasty and rectovaginoplasty, and also in panhysterectomy.

COMMENT

The authors do not offer their three additional criteria as proof that satisfactory surgical anesthesia will persist for this entire time and believe instead that the average safe interval for surgery lies approximately halfway between the average time in surgery and that recorded by these additional criteria. As such, 3 to 3½ hours of surgical anesthesia can reasonably be expected for surgery of the upper abdomen from 12 milligrams of pontocaine combined with 3 milligrams of neosynephrin. THE VALUE OF RESPIRATORY FUNCTION STUDIES IN PULMONARY SURGERY

STUDIES of various phases of respiratory function have played a significant role in the development of surgery of the lung. There has been a tendency for the surgeon to overlook the value of such investigations because special tests are not necessary in many patients submitted to pulmonary excision or collapse therapy. One tends to forget that our clinical evaluation of all cases has been indirectly influenced by the complete studies of pulmonary function which have been made in a few institutions.

Pulmonary tests have revealed a number of important facts. The surprising reduction in function which may result from the fixation of a relatively normal lung by a fibrous membrane over the pleura has been revealed. The unreliability of estimating function from the roentgen appearance of the lungs has become very evident. Fluoroscopic observations give more information, at least as far as ventilatory

factors are concerned. The importance of pulmonary emphysema in assessing the operative morbidity and mortality, and also in estimating the patient's breathing reserve after the postoperative period deserves wider recognition. It is through respiratory tests that we now know that overdistention of pulmonary tissue may interfere with function. These observations are the basis for the recommendation that thoracoplasty should follow pneumonectomy and occasionally even lobectomy in certain situations. The better functional adjustment which follows pulmonary resection in childhood as compared to adults has been demonstrated. The remarkable correlation between pulmonary ventilation and circulation has become manifest. These are but some things that have already been shown. Much additional data are highly desirable both in order to supply a more certain basis for the tentative conclusions which have already been arrived at and also for a critical review of clinical impressions from the physiologic standpoint.

In order to obtain the most help from a test designed to give information concerning the function of any organ, knowledge of the physiologic basis of that test is required. Since the function of organs is complex, a single test may give data about one factor only. Because disease processes may affect the different components of the respiratory mechanism in varying degree, no one test can be expected to elucidate the problem adequately. Yet the manner in which tests of pulmonary function are often utilized by the clinician indicates his failure to appreciate these facts.

From the physiological standpoint, pulmonary function can be divided into two categories

ries (1) ventilation or the mass displacement of air between the outside atmosphere and the interior of the lungs and (2) respiratory gas exchange, or the exchange of oxygen and carbon dioxide between the blood in the pulmonary capillaries and the air. It is obvious that these two are closely interrelated but various types of tests are necessary to obtain information concerning both components of pulmonary function¹

Determination of vital capacity has frequently been employed as a single test of lung function without a realization of the meager information thus obtained. The vital capacity is the amount of air which can be displaced by the lung during a single maximum ventilatory effort. It does not take the factor of time into consideration nor does it give any information about the patient's ability to transport oxygen from the alveoli to the blood in the pulmonary capillaries. Clinical observation of a patient's response to exercise will sometimes give more reliable information than an estimate of the vital capacity alone. An emphysematous patient who is dyspneic may have a relatively good vital capacity. Although the patient with emphysema may displace considerable air during a single maximum effort, it may take so long to get gases into and out of the lungs, that the ventilatory efficiency is actually poor. An estimation of maximum breathing capacity which is the total amount of air which can be moved by the lungs in a series of maximal inspirations and expirations per unit of time, is a simple and better way to determine the ventilatory function of the lung.

If respiratory function studies are to aid in determining the operative risk one must know to what extent the operative procedure alters or reduces such functions. This means that the effects of the anesthesia, the possibilities

of transient hypoxia, alterations in cardiocirculatory function, the degree of respiratory depression and the effect of reflexes must all be taken into consideration. Therefore, the value of physiological tests in estimating operative risk is limited at present because operative procedures which may be standardized as far as surgical technique is concerned are not as well standardized for accompanying physiological disturbances. The physiologically minded surgeon will avoid certain pitfalls that others may fail to consider. It should be stressed that hypoxia is often present without obvious cyanosis, that significant circulatory changes may occur without alterations in blood pressure or pulse and that both anesthesiologist and surgeon are often not fully cognizant of somewhat inadequate respiratory function.

The results of tests must be assessed in relation to the alterations which will occur from the operative procedure. If the pulmonary reserve is low the amount of functioning lung tissue removed by the lobectomy or pneumonectomy will be of greatest importance. Removal of a collapsed, airless lobe may result in little change in pulmonary function occasionally the function is slightly better after resection because all the pulmonary circulation then goes through ventilating lung tissue. Naturally there will be a temporary reduction in function during the operative and postoperative period. If removal of considerable functioning pulmonary tissue is contemplated, tests indicating poor reserve may warn the surgeon to modify the operative procedure or advise against operation. Mandatory operations, such as those for cancer, justify lessening the degree of consideration to be given to tests which show poor pulmonary function.

The distribution of the respiratory function between the two lungs must be determined by bronchospirrometry in some cases before an in-

¹Goldstein, E. de F. Coetzee, A. and Richards, D. W. Jr. *Medicine*, 1948, 27:1-242.

telligent recommendation can be given. This situation occurs most frequently in bilateral pulmonary tuberculosis. We may not be able to tell clinically and roentgenographically which lung is responsible for the greatest oxygen consumption. It may be found that although the total pulmonary function is fairly adequate, the side requiring collapse or excision is performing most of the respiratory function. In such a case the tests may save one from performing an operation which can only harm the patient even some cardiorespiratory deaths may thus be prevented.

The surgeon who was trained or works in an institution with a laboratory engaged in studies of respiratory function has a real opportunity. When tests of pulmonary function are performed on patients who are undergoing surgical treatment the physiological alterations which accompany disease and operative intervention are often clarified. If the surgeon is alert to his opportunities and constantly thinks along physiologic lines, the importance of many details in operative and postoperative care will become more and more evident as his knowledge and experience increases. The attitude that cardiorespiratory deaths following pulmonary or other surgery are in the majority unavoidable merely indicates a lack of knowledge. A failure to adjust accurately the intrapleural pressure after pneumonectomy, the acceptance of hypoxia during anesthesia, undue traction of the pulmonary hilum are but a few of the errors which are still made. The complications that the surgeon regards as not preventable are those whose mechanism of development he does not understand and therefore is unable to forestall. It would seem most desirable that adequate instruction in the clinical application of tests of pulmonary function be incorporated in the training of all those planning to perform intrathoracic operations.

Needless to say, much additional data should be obtained. At the present moment we are looking forward to further information concerning the function of the decorticated lung. We already know that a lung which appears well expanded following decortication may occasionally have poor function. The influence of long standing intrapulmonary disease and the duration of collapse must be evaluated. Also the pulmonary function after segmental resection requires more accurate appraisal. But probably most important of all is the need for data as to the physiologic disturbances which occur during operation. By this new knowledge the "unpreventable" complication of today may be avoided in the future.

HERBERT C. MAIER

SIMPLICITY IN SURGERY

MOST students of medicine and many others who spent their college days in Philadelphia in the 1920's and 1930's were privileged to attend the Saturday afternoon clinics of Dr. John B. Deaver. Hardly anyone who attended that clinic can forget Doctor Deaver's motto "Cut well, sew well, get well." This simple formula can well be preached today. The majority of patients who are operated upon with adequate indications and on whom the technical portion of the operation is carried out with due respect for the physiology of the organs involved and with care of the tissues handled will get well with relatively few postoperative complications.

It is surprising however to find that most medical students and interns believe that any abdominal operation requires intubation of one sort or another that practically all patients operated upon over the age of 60 should be given some form of anticoagulation therapy or femoral vein ligation and that practically

all operations should be followed by a period of penicillin, if not of streptomycin therapy and often the combination of both. The practice of preventing complications which never occur or never should occur is so widespread that the preoperative and postoperative care of patients has become a complicated procedure for the residents and interns, and more important a most troublesome time for the patient.

Due to an attempt to set up a routine which will take care of every emergency many a patient is unnecessarily disturbed by procedures which are not warranted in his particular case. It would seem worth while to individualize the care of each patient based on the knowledge and understanding of his particular problem. In the preoperative care of patients undergoing gastric resection passage of a tube into the stomach to provide suction drainage is rarely necessary unless the patient has an obstruction of the pylorus. After operation the tube is unnecessary unless vomiting becomes a prominent symptom. In the short loop antecolic Hofmeister type of gastrojejunal anastomosis vomiting occurs very infrequently. We have rarely found it necessary to use gastric suction postoperatively and we have never encountered an indication for the use of double lumen tubes for simultaneous gastric suction and jejunal feeding. The patients are able to take fluids and food on the second or third postoperative day without difficulty. It would seem unnecessary under such circumstances to add to a gastric resection and gastrojejunal anastomosis a jejunostomy for feeding purposes. A patient with a properly placed and properly performed gastrojejunostomy will take and retain nourishment sufficient for

his caloric needs by the third or fourth post operative day. One patient operated upon recently for an obstructing pyloric lesion gained twelve pounds within the first ten days following his operation.

At the time of operation gentleness in the handling of tissues and careful hemostasis, ligating only the bleeding vessel with fine ligatures, and much in the patient's convalescence. In the opinion of the writer the avoidance of all forms of crushing clamps is another factor which permits kindly healing and averts the traumatic edema which so greatly retards the tissues healing. This is true not only for operations in the upper intestinal tract but also for operations on the large and small bowel. Infections of the peritoneal cavity do not arise from contamination at the time of an open anastomosis if ordinary precautions are taken. Peritonitis from intestinal anastomosis arises from leakage at a suture line caused either by lack of attention to the blood supply or by an inadequate technique.

The advent of intestinal antiseptics and antibiotics has led to an unwarranted dependence upon these agents and to the disregard of the basic principles of surgical technique. It should be stressed that without an adequate basic technical procedure these substances are useless, and with an adequate technical procedure they usually are unnecessary.

This is written with no effort to decry the many valuable adjuncts to the care of the patient which are at our command. It is to emphasize however that the natural tendencies to repair and recovery function normally without much outside help. Most patients well operated upon will get well themselves, if they are allowed to! L. KRAZER FERGUSON

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE volume *Sterility and Impaired Fertility*¹ a second edition is the result of collaboration by British specialists working in different parts of the field. They have succeeded in demonstrating the fact that both the etiological factors and therefore the therapeutic indications are distributed over a very wide field in which general medicine, gynecology, urology, endocrinology and psychology may all be involved. All the recent advances in seminology and reproductive physiology are included with special reference as to the interpretation and significance of postcoital tests and the more recently developed invasion tests as worked out by the authors. Details on the technique of semen analysis are clearly presented as are all the newer adjuncts to the determination of ovulation including cyclical temperature records. The presentation is directed primarily toward the general practitioner but should prove equally valuable to the gynecologist and the urologist. It is a comprehensive volume which in a most effective way combines a theoretical consideration of reproductive physiology with the practical application of the principles presented. The balance between theory and practice is well maintained although one gathers that the authors are more enthusiastic over endocrine therapy and x ray therapy than most groups in America. All in all however this is a very useful and complete volume on a very common and important problem. It is well written and well organized and the statement in the first foreword that it is not easy to read is perhaps the one to which the reviewer took chief exception.

STUART AXEL.

THE small handbook of 186 pages *Management in Obstetrics*² deals essentially with the handling of the complications of pregnancy and labor. As the writer states, "It tends to be dogmatic and alternative treatment is not described." In his preface the author states further "It is not claimed that the lines of treatment described are beyond question the best; they are merely those in which I believe myself." The above descriptions applied by the author fit the volume quite well. The book is recommended to the author's students. Whether it has a wider field of usefulness is a debatable question.

DOUGLAS P. MURPHY

STERILITY AND IMPAIRED FERTILITY. PATHOGENESIS, INVESTIGATION AND TREATMENT. By Cedric Lane-Roberts, Albert Shartman, Kenneth Walker, B. P. Wiesner and Mary Barton. 3d ed. New York and London: Paul B. Hoeber Inc., 1948.
MANAGEMENT OF OBSTETRICS. By Andrew M. Clay, M.D., F.R.C.S., F.R.C.O.G. London, New York, and Toronto: Geoffrey Cumberlege, Oxford University Press, 1948.

THE book *Neurosurgical Pathology*³ is the second of three volumes intended to cover the field of neuropathology and it is directed to the neurosurgeon. In this volume the neurosurgeon is to find a dynamic approach to neurosurgical pathology and a clinicopathological correlation of all common conditions coming into his sphere of activity. Had this been true it would have been a most acceptable achievement unfortunately it falls short of the mark. The question of whether there is such a thing as neurosurgical as opposed to neurological or medical neuropathology is open to considerable debate. Most of those working in the general field of neurology would regard this as carrying specialization too far. The only excuse for carrying specialization to this extreme would be a very complete, careful, and detailed exposition of all phases of this limited section of the subject, with reference to and discussion of the most recent work of other investigators also working in the field.

The book is divided into five chapters: cerebral swelling, 30 pages; central nervous system injuries, 110 pages; tumors of the central nervous system, intracranial tumors, 163 pages; cerebral abscess, 16 pages; hydrocephalus, 5 pages. The number of pages is given to show the relative emphasis. The bibliography contains about 350 references. The format of the volume is excellent and the illustrations are excellently reproduced. As a rule the illustration is on the same or the adjoining page to the written text, which is an obvious advantage.

The author has a very definite point of view concerning injury to the central nervous system. Cerebral swelling is rescued from the chaos of cerebral edema and described in detail. It contains the main thesis of the author's views of injuries which is that cerebral swelling can be divided into three stages: tumefaction, edema, and liquefaction, which are parts of the same biological process. The first stage consists of parenchymatous changes and vascular alterations characterized by vasoparalysis of veins and capillaries in the cerebral substance with congestion and stasis followed by swelling and degeneration of the endothelial cells. The other two stages follow naturally from this. In all stages cerebral swelling occurs principally in the white matter because of the discrepancy between its relatively poor blood supply and the much more vigorous interlacing supply of the cerebral cortex. This point is beautifully illustrated. The argument is supported by photomicrographs which unfortunately would not appear as conclusive

³NEUROSURGICAL PATHOLOGY. By I. Mark Scheinker, M.D. Springfield, Ill.: Charles C. Thomas, 1948.

to others as to the proponents of this view. The discussion of transtentorial herniation is well done and contains valuable information.

The chapter on injuries of the central nervous system again emphasizes the author's particular leanings and most of the references are to his own particular work in this field. Head injuries are classified according to his views in which reversible changes with vasoparalysis may go on to the irreversible changes of vasothrombosis with disseminated foci of tissue destruction. The profuse illustrations are excellent and clearly show the points under discussion. Sometimes a point appears to be carried too far the inference that midbrain hemorrhage may be secondary to transtentorial swelling is acceptable, but in trauma it may also occur directly. The illustrations do not always support the legends: time cannot be told by one picture. However, in spite of a certain bias, this is a good chapter and of great interest to any neurosurgeon.

Spinal cord injuries are briefly mentioned with reference to vasoparalysis but nothing is added to the confusion concerning spinal cord concussion. The comments of Bradford and Spurling on the lumbar intervertebral disc herniation syndrome are repeated.

The chapter on intracranial tumors is well illustrated and although the author specifically states that he is only interested in showing concisely the histopathological features of the more commonly observed tumors, he takes eight pages to discuss the subependymoma of Schönlanker. The rest of the chapter except the unnecessary reference to infundibuloma, follows the classical monographs of Bailey and Cushing and others of this school. There are short chapters on cerebral abscess and hydrocephalus.

Clinical considerations are added to each subject heading and although these may be helpful to some there is a tendency to put the emphasis in the wrong place. For instance, "Complete surgical removal of a medulloblastoma is often impossible. In 1948 it has been practically always impossible. A case of astrocytoma cerebelli is mentioned with a phenomenally long life history—an exceptional case. Preoperative irradiation of presumed medulloblastomas is mentioned in spite of warnings of the dangers.

There is a real question whether in consideration of a limited field the subject should not be more completely dealt with and more attention given to the recent work of others. There are some serious omissions in the bibliography. There is no reference to extradural tumors of the spinal cord, extradural abscess, peripheral nerve tumors or injuries or congenital defects of the central nervous system, all of which are of interest to the neurosurgeon. The first 120 pages of this book could be expanded, completed, and published as a separate monograph, it is interesting and stimulating and further work by scientists, in the direction suggested by Dr. Schönlanker may confirm his point of view.

ADDISON VEE BROOKINGS.

THE authoritative reference work on *Viral and Rickettsial Infections of Man* should be welcomed by practicing internists in the medical field as a whole. The companion volume edited by René J. Dubos deals with bacterial and mycotic infections. The subjects covered in the present work are as follows:

General principles are described by Dr. Rivers; methods used in the study of virus diseases are described by W. M. Stanley and Max A. Lauffer; diagnostic methods are reviewed by Joseph E. Smadel; chickembryo techniques are analyzed by E. W. Goodpasture and G. John Buddingh; tissue culture methods are reviewed by John F. Enders, and the discussion of a complete list of virus diseases, central nervous system and general virus diseases constitute the larger portion of the volume.

It is evident that the campaign against the bacterial diseases has made rapid progress in the last decade. The fight against virus diseases, however, is still in its early stages and somewhat analogous to the situation in the early years of this century when the treatment of bacterial diseases was primitive. The general knowledge, however, of the viruses and their diseases has expanded rapidly. It is to be hoped that revolutionary methods in diagnosis and therapy will soon be available. The present volume should contribute greatly to this much needed progress.

PART STARR.

THE five hundred page first edition of *The Radiology of Bones and Joints* published nearly fifteen years ago has now expanded in this fourth edition to 760 pages, with 615 illustrations, constituting a thoroughly up-to-date treatise on the x-ray aspects of bone and joint lesions. The author who has become well and favorably known to American readers through his personal appearances in various parts of this country has made many valuable contributions to radiology. Consistently maintained throughout this book is the author's skepticism of the need of biopsy. He himself served a long apprenticeship in pathology and became convinced that the wider our knowledge of roentgenographic appearances, particularly of bones and joints, the less need there should be to resort to biopsy or other painful preliminary investigations. He urges the diagnostic value of periodic observation of roentgenographic changes, calling attention to the fact that renewed x-ray study after the lapse of a few weeks may supply the clinician with striking roentgenographic evidence, although the first roentgenogram may have been of little or no positive value and be also emphasize that although various pathological conditions present similar clinical signs, fortunately their respective roentgenographic appearances are distinctly characteristic.

VIRAL AND RICKETTSIAL INFECTIONS OF MAN. Edited by Thomas M. Rivers, M.D. Philadelphia, London, and Montreal: J. B. Lippincott Co., 1948.

THE RADIOLOGY OF BONES AND JOINTS. By James F. Brayford, M.D. Ph.D. F.R.C.P. F.I.C.R. 4th ed. Baltimore: The Williams & Wilkins Co., 1948.

This publication constitutes the most pretentious and authoritative reference book on bone and joint pathology in the English language, and as such should find a place on the desk of every radiologist and orthopedist, as well as many others in the field of general medicine.

JAMES T. CASE.

THE second edition of *Abdominal Operations*¹ is an authoritative and practical book with contributions by outstanding surgeons of England, Australia and America.

This volume of 1231 pages is devoted primarily to a detailed presentation of modern surgical technique for abdominal operations. It is illustrated by 468 figures totaling 1051 illustrations. The original vivid and life like drawings by Miss Pauline Larivière and Miss M. C. McLarty are an outstanding feature of the book. The large type and wide spacing of printed lines afford easy reading and clear explanation. The presentation of references throughout the text in parenthetical manner instead of placing them at chapter endings or as footnotes, is not objectionable to the reader and permits prompt recognition of the source and date of reference work.

Part I is devoted to abdominal incisions and covers the principles and details of various operative approaches as well as the closure of wounds and the management of wound complications.

Part II is composed of 395 pages concerning the stomach and duodenum and discusses acute dilatation of the stomach, acute gastritis, foreign bodies, congenital lesions, diverticula, injuries, fistula, ulcers and tumors. The chapter on vagotomy was written by Dragstedt, and the chapter on cancer of the cardiac end of the stomach and lower esophagus by Tanner of London. The chapter on the management of bleeding ulcer shows evidence of the Meulengracht influence on medical treatment and emphasizes Gordon Taylor's attitude regarding surgical treatment.

Part III discusses splenectomy from the standpoint of physiologic effects, complications and results as well as the surgical technique. The splenic diseases of surgical importance are reviewed.

Part IV is devoted to the pancreas and covers anomalies, calculi, cysts and fistulas, inflammatory lesions and tumors.

Part V presents the surgical technique of operations on the gall bladder and bile ducts and includes discussion of anomalies, injuries, tumors, inflammatory lesions and stones as well as the results achieved by operative treatment.

Part VI is devoted to the liver. This is a relatively short chapter on injuries, liver abscess, neoplasms, and cysts. There is an excellent discussion of hydatid disease of the abdomen by Drew of Australia. One might wish for a short discussion of liver function tests of surgical significance.

Parts VII and VIII cover the vermiform appendix and the peritoneum, mesentery and omentum.

ABDOMINAL OPERATIONS. By Rodney Mainrot, F.R.C.S. (Eng.) ed. ed. New York Appleton-Century-Crofts, Inc., 1943.

Part IX reviews the treatment of external abdominal hernia of the inguinal, femoral, umbilical and ventral types. The author is an advocate of the floss silk lattice repair for direct inguinal hernia, but does not neglect the other types of repair.

Part X is devoted to the intestines. Nine chapters in this section review the management of surgical lesions in the small intestine, colon and rectum. The discussion of congenital intestinal obstruction was written by Cockinis of London and the discussion of synchronous combined abdominoperineal resection of the rectum by Lloyd Davies of London.

Part XI is composed of three chapters. Postoperative chest complications of abdominal surgery and their management are presented by Brock of London. Diaphragmatic hernia is reviewed by Harrington. The section is concluded by a short chapter on portal hypertension and portacaval shunts.

While the emphasis of this work is on the technical steps of surgical operations, each of the sections contains adequate descriptions of diagnostic procedures, preoperative and postoperative care, complications, and end results to round out an excellent and valuable addition to any surgical library. The book will be very popular with general and abdominal surgeons and should be on the desk of every surgical resident.

EDWARD W. GREEN.

A TEXTBOOK of anesthesiology based upon the preceding editions by the same authors includes the addition of sections on the use of curare and the legal responsibilities of the anesthesiologist under British law together with new material in existing chapters. Obsolete material has been eliminated. There has been considerable expansion of the chapter on regional anesthesia. The physiology of various anesthetic agents together with principles, techniques, and methods of administration are covered clearly so that the applicability, advantages and disadvantages of the agents are readily available to the reader.

Of disadvantage to the practitioner in this country is general restriction to British types of apparatus and nomenclature as well as the illustrations which are of British equipment not generally used or available here. Of especial value to a student in the early phases of his training are the chapters on anesthesia for dentistry, the abnormal incidents of anesthesia and the sequelae of anesthesia.

The *Textbook of Anaesthetics*² is interestingly written and possesses a quality of expression which renders it easily readable.

FRANCIS M. SELLERS.

THE first large textbook of endocrinology published in England, *The Practice of Endocrinology* edited by Greene,³ is intended for the general practitioner. Collaborators include Drs. A. C. Crooke

¹TEXTBOOK OF ANAESTHETICS. By R. J. Minnitt, M.D. and John Giles, M.D. 7th ed. Baltimore: The Williams & Wilkins Co., 1943.

²THE PRACTITIONER TEXTBOOK. THE PRACTICE OF ENDOCRINOLOGY. Edited by Raymond Greene, M.A., D.M., M.R.C.P. London: Eyre & Spottiswoode, Ltd., 1943.

to others as to the proponents of this view. The discussion of transtentorial herniation is well done and contains valuable information.

The chapter on injuries of the central nervous system again emphasizes the author's particular leanings and most of the references are to his own particular work in this field. The large type and wide spacing of printed lines afford easy reading and clear explanation. The presentation of references throughout the text in parenthetical manner instead of placing them at chapter endings or as footnotes is not objectionable to the reader and permits prompt recognition of the source and date of reference work.

Part I is devoted to abdominal incisions and covers the principles and details of various operative approaches, as well as the closure of wounds and the management of wound complications.

Part II is composed of 395 pages concerning the stomach and duodenum and discusses acute dilatation of the stomach, acute gastritis, foreign bodies, congenital lesions, diverticula, injuries, fistula, ulcers and tumors. The chapter on vagotomy was written by Dragstedt, and the chapter on cancer of the cardiac end of the stomach and lower esophagus by Tanner of London. The chapter on the management of bleeding ulcer shows evidence of the Meulen-gracht influence on medical treatment and emphasizes Gordon Taylor's attitude regarding surgical treatment.

Part III discusses splenectomy from the stand point of physiologic effects, complications and results as well as the surgical technique. The splenic diseases of surgical importance are reviewed.

Part IV is devoted to the pancreas and covers anomalies, calculi, cysts and fistulas, inflammatory lesions and tumors.

Part V presents the surgical technique of operations on the gall bladder and bile ducts and includes discussion of anomalies, injuries, tumors, inflammatory lesions and stones as well as the results achieved by operative treatment.

Part VI is devoted to the liver. This is a relatively short chapter on injuries, liver abscess, neoplasms, and cysts. There is an excellent discussion of hydatid disease of the abdomen by Dew of Australia. One might wish for a short discussion of liver function tests of surgical significance.

Parts VII and VIII cover the vermiform appendix and the peritoneum, mesentery and omentum.

ABDOMINAL OPERATIONS. By Rodney Malcolm, F.R.C.S. (Eng.) 2d ed. New York: Appleton-Century-Crofts, Inc., 1913.

Part IX reviews the treatment of external abdominal hernia of the inguinal, femoral, umbilical and ventral types. The author is an advocate of the floss silk lattice repair for direct inguinal hernia, but does not neglect the other types of repair.

Part X is devoted to the intestines. Nine chapters in this section review the management of surgical lesions in the small intestine, colon and rectum. The discussion of congenital intestinal obstruction was written by Cockin of London and the discussion of synchronous combined abdominoperineal resection of the rectum by Lloyd Davies of London.

Part XI is composed of three chapters. Postoperative chest complications of abdominal surgery and their management are presented by Brock of London. Diaphragmatic hernia is reviewed by Harrington. The section is concluded by a short chapter on portal hypertension and portacaval shunts.

While the emphasis of this work is on the technical steps of surgical operations, each of the sections contains adequate descriptions of diagnostic procedures, preoperative and postoperative care, complications, and end results to round out an excellent and valuable addition to any surgical library. The book will be very popular with general and abdominal surgeons and should be on the desk of every surgical resident.

EDWARD W. GIBBS.

A TEXTBOOK of anesthesiology based upon the preceding editions by the same authors, includes the addition of sections on the use of curare and the legal responsibilities of the anesthesiologist under British law together with new material in existing chapters. Obsolete material has been eliminated. There has been considerable expansion of the chapter on regional anesthesia. The physiology of various anesthetic agents, together with principles, techniques and methods of administration are covered clearly so that the applicability, advantages and disadvantages of the agents are readily available to the reader.

Of disadvantage to the practitioner in this country is general restriction to British types of apparatus and nomenclature as well as the illustrations which are of British equipment not generally used or available here. Of especial value to a student in the early phases of his training are the chapters on anesthesia for dentistry, the abnormal incidents of anesthesia, and the sequelae of anesthesia.

The *Textbook of Anaesthetics*² is interestingly written and possesses a quality of expression which renders it easily readable.

FRANCIS M. SELLERS.

THE first large textbook of endocrinology published in England *The Practice of Endocrinology* edited by Greene³ is intended for the general practitioner. Collaborators include Drs. A. C. Crooke

TEXTBOOK OF ANAESTHETICS. By R. J. Minnitt, M.D. and John Gibbs, M.D. 7th ed. Baltimore: The Williams & Wilkins Co., 1913.

THE PRACTITIONER TEXTBOOK. THE PRACTICE OF ENDOCRINOLOGY. Edited by Raymond Greene, M.A., D.M., M.R.C.P. London: Eyre & Spottiswoode, Ltd., 1913.

Donald Hunter R. D. Lawrence J. M. Robson, F. F. Rundle, and P. H. Sandifer. Discussed in separate chapters followed by references, are the hypothalamus, pituitary gland, adrenals sex and reproduction, the thyroid gland, carbohydrate metabolism and diabetes mellitus, calcium metabolism and the parathyroid glands, the thymus and pineal body and adiposity. Although stress is laid on prac-

tice rather than on theory the related anatomy pathology and physiology are clearly and ably presented.

Clinical pictures are well described and principles of treatment are sound and conservative, reflecting the combined experience of members of the staffs of many of the London hospitals.

WALTER H. NADLER.

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

DEEP MASSAGE AND MANIPULATION ILLUSTRATED. By James Cyrtax, M.D., B.Ch. (Cantab.) 3d ed. New York and London Paul B. Hoeber Inc., 1948.

SURGERY OF THE HAND. By Sterling Kennell, M.D. 2d ed. Philadelphia, London, and Montreal J. B. Lippincott Co., 1948.

MAYO CLINIC DIET MANUAL. By the Committee on Diets of the Mayo Clinic. Philadelphia and London W. B. Saunders Co., 1949.

BLOOD TRANSFUSION. By Elmer L. McGowan, M.D. Robert C. Hardin, M.D., and John B. Abner, M.D. Philadelphia and London W. B. Saunders Co., 1949.

OBSTETRIC AMALGAMA AND ANESTHESIA, THEIR EFFECTS UPON LABOR AND THE CHILD. By Franklin F. Snyder, M.D. Philadelphia and London W. B. Saunders Co., 1949.

THE BUSINESS SIDE OF MEDICAL PRACTICE. By Theodore Wiprud, 2d ed. Illustrated. Philadelphia and London W. B. Saunders Co., 1949.

OUTLINE OF ARABIC CONTRIBUTIONS TO MEDICINE AND THE ALLIED SCIENCES. By Amin A. Khalilallah, B.A., M.D. F.A.C.S. Beirut American Press, 1948.

COLLECTIVE REVIEW

VASCULAR MALFORMATIONS AND VASCULAR TUMORS OF THE GASTROINTESTINAL TRACT

ROBERT W GENTRY M.D., MALCOLM B DOCKERTY M.D., and
O THERON CLAGETT M.D., F.A.C.S., Rochester Minnesota

VASCULAR malformations and vascular tumors are rarely encountered in the gastrointestinal tract and no single investigator has had the opportunity to study more than a few cases. The relatively high incidence of serious clinical complications and malignant disease associated with these lesions was appreciated only after an extensive review of the literature and analysis of available histopathologic material. A comprehensive analysis of various methods of treatment and prognosis has been undertaken to assist further in securing satisfactory answers to the remaining unsolved problems.

MATERIALS AND METHODS OF STUDY

Vascular lesions involving the gastrointestinal tract have been reported since 1839 however their infrequent occurrence made it seem desirable to summarize every case report encountered in the available literature and thus to secure basic data for statistical analysis and for formulation of accurate conclusions. Table I gives a brief classification of all cases by type of lesion, by source, and by certain other characteristics. Table II summarizes the case reports appearing in the literature from 1839 to 1945, inclusive.

Abridgment of portion of thesis submitted by Dr. Gentry to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Surgery.

From the Department of Surgery Mayo Foundation, and the Section on Surgical Pathology and Division of Surgery Mayo Clinic.

The material utilized in this review included also the case records from the Mayo Clinic files through June, 1945 wherein a diagnosis had been made of either a vascular malformation or a vascular tumor of the gastrointestinal tract. Records of 106 vascular lesions were found in a review of approximately 1,400,000 case records. This group included 46 patients with vascular lesions observed at the time of surgical treatment, whereas, during a further study of more than 10,000 records of autopsies which were performed in the 30 year period from 1925 through 1944 60 more vascular tumors or vascular malformations of the gastrointestinal tract were found. No esophageal varices were included in this study.

Both the surgical and autopsy specimens were examined and classified according to their histopathologic structure and their location in the gastrointestinal tract.

A clinical review and analysis of these 106 cases constitute the basis for the second part of this study, summarized in Table III.

PATHOLOGY

The description of the pathologic processes which are classified under the heading of vascular malformations and vascular tumors presents unusual difficulties. Vascular abnormalities may display either pronounced neoplastic properties of their own or subordinate themselves to complicated histopathologic changes which occur in various associated organs and tissues. The scope of

ing blood vessels, whereas 'angiomatosis' refers to the formation of outgrowths of ectopic endothelium-lined blood-containing spaces. The telangiectatic lesions are capillary in structure but, microscopically channels larger than normal are demonstrable.

As early as 1852 Rokitsansky (208) observed telangiectatic lesions in the mucous membrane of the intestine.

Interest in the hereditary type of hemorrhagic telangiectasia dates from a paper published in 1901 by Osler (184) although Rendu, in 1896 was the first to associate familial epistaxis and multiple telangiectasia of the mucous membrane in the gastrointestinal tract.

Still earlier in 1869, Wilson reported the first instance of gastrointestinal bleeding from telangiectatic lesions and called the condition 'eruptive angiomata.' Becker in 1926 and Magnusson, in 1934, collected the reports of cases from the literature and classified the various types of generalized and hereditary telangiectasia. Renshaw in 1939 reported the first case in which the lesion was seen with the gastroscope while Schuster Fox, and Goldstein listed the reports of fatal cases involving the gastrointestinal tract.

Pathogenesis and classification. Lanceplaine in 1904, advanced three theories for the patho-

genesis of generalized telangiectasia: (1) disturbance of the vasomotor nerves, (2) embarrassment of the general circulation, and (3) toxicity.

Hanes, in 1909 and later Gjessing in 1916 drew attention to the absence of elastic and muscular elements in the vessel walls in cases of hereditary telangiectasia.

The term 'telangiectasia' was soon recognized as a relative term, for few adults have not suffered a certain degree of peripheral vascular ectasia, and it has become evident that there are many pathologic lesions which can be grouped under this heading.

A consideration of those lesions which produce gastrointestinal hemorrhage centers primarily around the hereditary hemorrhagic group which form the basis for the collected reports of cases and for the histopathologic study presented in this review.

Hereditary hemorrhagic telangiectasia. Three classical requisites are necessary to establish a diagnosis of hereditary hemorrhagic telangiectasia: (1) history of repeated hemorrhages, (2) telangiectatic lesions of the mucous membrane of the nasal or oral cavities, viscera, or skin, and (3) a familial occurrence.

Fitz Hugh has shown that atavism unquestionably exists so that, although the disease is heredi-

this review will be limited primarily to a classification and clinicopathologic descriptions of those vascular lesions which involve the gastrointestinal tract. However a brief general discussion of histogenesis is presented with each group in order to assist with a more accurate and comprehensive classification of these lesions.

CLASSIFICATION

One of the most useful methods of classification of tumors is based on histogenesis; however a consideration of the histology and architecture of vascular lesions has been valuable in determining prognosis and methods of treatment.

Brown classified the hemangiomas of the intestinal tract according to their effect on the surrounding substrate and considered these lesions primarily from the standpoint of possible surgical intervention. Gross and Wolbach compared average sections in different tumors and grouped together those which matched most closely Kalfje's classification, which has been stated to be essentially that of Oberndorfer has many favorable attributes however he included, in a benign group some vascular lesions which many pathologists consider to be malignant.

The following classification, based on histopathologic detail, tends to emphasize the value of certain forms of treatment and the resulting prognosis.

Benign vascular lesions

- A. Telangiectasis (hereditary and nonhereditary types)
- B. Hemangioma
 1. Capillary hemangioma (simplex, most by single)
 2. Mixed capillary and cavernous hemangioma
 3. Cavernous hemangioma
 - a. Multiple phlebectasis (small cavernous)
 - b. Simple polypoid (single cavernous)
 - c. Diffuse expansive (single contiguous)
 - d. Diffuse expansive (multiple non-contiguous)

Malignant vascular lesions

- A. Hemangioendothelioma
- B. "Benign metastasizing hemangioma"
- C. Kaposi's sarcoma
- D. Angiosarcoma

BENIGN VASCULAR TUMORS

Phillips (192) in 1839, described what was perhaps the first vascular tumor of the gastrointestinal tract reported in the literature. An indoor

servant in the service of a nobleman had three severe hemorrhages from straining at stool. A tumor the size of a French walnut was found in the rectum and irritation from neighboring parts made it tense and turgid. This vascular lesion had a lived, irregular fungous appearance and was attached to five-sixths of the anal margin. It was removed by needle ligature.

Syme in 1854, and Quain, in 1855, reported 3 more cases of soft vascular rectal tumors.

Rokitansky (107) in the English translation of his manual of pathologic anatomy published in 1855 mentioned the occurrence of vascular tumors in both the stomach and intestines. Regarding the stomach he wrote

"Erectile tissue is either developed in the free ends of polypi, or the mucous membrane degenerates into it on a large surface, upon which the erectile tumor is attached by a broad base, or only by a very short neck or stalk. It is the common seat of encephaloid infiltration."

R. H. Fitz, in 1872, reviewed a case report published by Laboulbène in which a 64 year old man died of a single massive hemorrhage from an ulcerated cavernous hemangioma of the duodenum.

Virchow Aebv Thoma, Ribbert, and many others, before the turn of the nineteenth century contributed to the basic concepts of pathogenesis and histopathology of vascular malformations and tumors.

Brown, in 1924, classified the hemangiomas of the small and large intestine into four groups and collected reports of 19 cases from the literature.

Geschlechter and Keasbey reviewed the data on 570 tumors of the blood vessels listed in the surgical and autopsy records of the Johns Hopkins Hospital. The majority of these tumors were located in the subcutaneous parts of the body although the liver contained 109 of the lesions. Only 10, or less than 2 per cent, were divided between the spleen, intestines, and mesentery.

Kalfje in 1936 and after a careful study of the world literature, collected reports of only 74 cases of vascular tumors involving the gastrointestinal tract. He emphasized the roentgenographic appearance of phleboliths in these lesions and its possible value in diagnosis before surgical exploration.

In 1941 Morton and Burger described the first hemangioma seen during gastroscopy.

Christopher in 1942, found reports of 11 cases of vascular tumors involving the gastrointestinal tract which were cited in the literature since the comprehensive review by Kalfje.

Telangiectasis The term telangiectasis is generally considered to refer to dilatation of exist-

ing blood vessels, whereas angiomatosis refers to the formation of outgrowths of ectopic endothelium lined blood-containing spaces. The telangiectatic lesions are capillary in structure but microscopically channels larger than normal are demonstrable.

As early as 1852 Rokitanaky (208) observed telangiectatic lesions in the mucous membrane of the intestine.

Interest in the hereditary type of hemorrhagic telangiectasis dates from a paper published in 1901 by Osler (184) although Rendu in 1896 was the first to associate familial epistaxis and multiple telangiectasia of the mucous membrane in the gastrointestinal tract.

Still earlier in 1869, Wilson reported the first instance of gastrointestinal bleeding from telangiectatic lesions and called the condition eruptive angioma. Becker in 1926 and Magnusson in 1934, collected the reports of cases from the literature and classified the various types of generalized and hereditary telangiectasia. Renshaw in 1939 reported the first case in which the lesion was seen with the gastroscope, while Schuster Fox and Goldstein listed the reports of fatal cases involving the gastrointestinal tract.

Pathogenesis and classification. Lanceplaine, in 1904, advanced three theories for the patho-

genesis of generalized telangiectasis (1) disturbance of the vasomotor nerves (2) embarrassment of the general circulation, and (3) toxicity.

Hanes in 1909 and later Gjessing, in 1916 drew attention to the absence of elastic and muscular elements in the vessel walls in cases of hereditary telangiectasia.

The term "telangiectasis" was soon recognized as a relative term, for few adults have not suffered a certain degree of peripheral vascular ectasia and it has become evident that there are many pathologic lesions which can be grouped under this heading.

A consideration of those lesions which produce gastrointestinal hemorrhage centers primarily around the hereditary hemorrhagic group which form the basis for the collected reports of cases and for the histopathologic study presented in this review.

Hereditary hemorrhagic telangiectasia. Three classical requisites are necessary to establish a diagnosis of hereditary hemorrhagic telangiectasia. (1) history of repeated hemorrhages, (2) telangiectatic lesions of the mucous membrane of the nasal or oral cavities, viscera, or skin and (3) a familial occurrence.

Fitz Hugh has shown that atavism unquestionably exists so that, although the disease is heredi-

pulmonary tissue in the skin of reptiles and lower forms.

In an extensive study of patients with cutaneous hemangiomas Watson and McCarthy found that more than 73 per cent of the vascular lesions were present at birth. This strongly supports the theory for congenital origin of all vascular tumors.

According to Cockayne, there seem to be no long pedigrees showing a direct or indirect inheritance of any of the common forms of vascular tumors. The number of twins in which obvious angiomas have been present is too small to permit definite conclusions.

Comparatively little attention has been paid to the histologic changes which take place during the growth and development of hemangiomas.

The evolution of lesions appearing on the surface of the body has been exhaustively studied by Groes and Wolbach. They postulated the following factors which may influence or arrest the development of hemangiomas: first, a deficient blood supply may convert the surrounding tissue into a dense fibrous layer and thereby may produce perivascular and endovascular thickening of the endothelial lining with resultant progressive obliteration; second, endothelial cells may proliferate and become vacuolated into embryonic capillary hemangiomas; and third, embryonic capillary hemangiomas may establish a connection with the circulation which, under pressure, causes the endothelium to become thinner and cavernous blood spaces to enlarge to form cavernous hemangiomas.

Capillary hemangioma. The capillary form of hemangioma consists of a new growth of small closely packed blood vessels with well differentiated endothelium. Hyperplasia of these endothelial lining cells is a constant feature and may tend to obliterate the vascular spaces. The connective tissue stroma is deficient in elastin and muscular tissue. The general structure of the tumor is more embryonic than that of the cavernous hemangioma.

Capillary hemangiomas often appear as single, discrete, encapsulated tumors in the gastrointestinal tract. They arise from outpocketings of the submucosal vascular plexus and enlarge toward the lumen of the associated hollow viscus. Their outside diameter may vary from that of 1 by 1 cm. plaques to that of pedunculated tumors measuring 11 by 3 by 2 cm. which tend to cause intussusception and obstruction.

The capillary hemangiomas which develop in the esophagus and small intestine are generally smaller and produce symptoms earlier than those found in the stomach and colon. Ulceration of

the mucosal surface was present in more than one half of the cases cited in the literature and in this study.

Differential diagnosis. Broders observed in 1923 that it is sometimes difficult to distinguish melanopithelioma from capillary hemangioma, especially if the endothelial cells have picked up blood pigment. Microscopic sections of a melanopithelioma, when stained, will be iron free, whereas those of a hemangioma contain iron.

Capillary hemangiomas are sometimes mistaken for hemangioendotheliomas. A study of their histopathology as it relates to invasion, metaplasia, atypical mitosis, and local or distant metastasis will assist in the differentiation.

Distribution symptoms and treatment. Data on 283 benign vascular tumors were collected from the literature and from the records used in this study. Eighteen, or 6 per cent, of these lesions were classified as capillary hemangiomas. These tumors were found to occur in every anatomic segment of the gastrointestinal tract.

The symptoms, complications, and treatment of capillary hemangiomas depend primarily on the specific location of the lesions in the gastrointestinal tract and will be considered in another section of this review; however, certain general observations are of interest when each separate group of pathologic lesions is considered. Sixteen or 89 per cent, of the patients with capillary hemangioma experienced symptoms from chronic blood loss, perforation, or intestinal obstruction. Surgical extirpation was possible in 14, or 78 per cent, of the cases, whereas 2 patients died, one of esophageal perforation and the other a 12 day old infant, of hemorrhage from a gastric hemangioma.

Mixed capillary and cavernous hemangiomas. The classification of hemangiomas depends primarily on grouping different lesions which have the same average cellular arrangement. A cut section through a mixed capillary and cavernous hemangioma presents solid areas of hyperplastic endothelial cells and semi-obliterated vascular spaces which alternate with large blood filled sinuses lined by a single layer of endothelial cells and supported by connective tissue septa containing moderate amounts of elastin and sometimes muscular tissue.

The mixed capillary and cavernous hemangiomas like the capillary hemangiomas, arise from the submucosal vascular plexus, are often encapsulated in a thin layer of fibrous tissue, tend to enlarge toward the lumen of the contiguous viscus, may become pedunculated, and frequently ulcerate through the overlying intestinal mucosa.

Eighteen mixed capillary and cavernous hemangiomas were found during this review. The majority were located in the stomach, small intestine, and appendix. It is interesting to note that in 8 of the patients clinical signs and symptoms of subacute intestinal obstruction developed. Surgical extirpation of the vascular lesion was successful in each of these cases. Two other patients in whom exploration was performed following a tentative diagnosis of acute appendicitis each had a primary vascular tumor of the appendix which had undergone torsion and infarction. Three patients died as a result of complications associated with mixed capillary and cavernous hemangiomas.

Cavernous hemangiomas. The cavernous forms of hemangioma consist of large blood-filled spaces or sinuses lined by single or multiple layers of endothelial cells. Their supporting stroma is composed of scant connective tissue septa which may contain smooth muscle fibers. These tumors, like the capillary hemangiomas, must be distinguished from lesions which develop after regenerative, inflammatory or circulatory disturbances.

Growth occurs at the periphery of cavernous hemangiomas by angioblastic proliferation, dilatation of the capillary spaces, and fusion of the intervascular connective tissue walls to form septa. Degenerative and sclerosing changes may appear early in the evolution of these tumors and are represented by coagulation of blood in the cavernous spaces, overgrowth of fibrous tissue hyalinization, edema, and foci of calcification.

Four histopathologic subdivisions of the cavernous tumors were made in this review.

1. Cavernous hemangiomas of the multiple phlebectasia type. Cavernous hemangiomas of this group are characterized by a multiplicity of small discrete lesions found in any or all segments of the gastrointestinal tract. As many as 50 separate tumors have been counted in a 20 cm. length of the small intestine. The majority of lesions are confined to the submucosa and rarely exceed 1 cm. in diameter.

A close association with the normal vascular segments of the bowel is easily demonstrated by compression of the tumors at the time of surgical treatment. They are seen to blanch and, with release of pressure, immediately to refill with blood. Moeller considered them to be baglike distensions attached to venous vessels at only one point; however, on careful examination of fixed specimens, more than one communication with the submucosal capillary network may be identified, and the lesions have the same multiplicity of associated sinuses and connective tissue septa and

the same deficiency of elastin and muscular tissue as do other cavernous hemangiomas.

Increased venous pressure in the portal circulation might be considered an etiologic factor; however, no lesions have been observed in association with either Banti's syndrome or advanced cirrhosis of the liver. The lesions are consistently larger than the lesions obtained at biopsy from patients having multiple hereditary telangiectatic lesions and there is no known familial tendency.

The incidence of these lesions has been difficult to estimate since they are often disregarded in the postoperative notes and frequently are overlooked during postmortem examinations. Moeller found only 3 cases during 12,000 to 15,000 autopsies, whereas in our study of more than 10,000 autopsy reports, 49 cases were encountered. Reports of 94 cases were collected for this review; these cases represent approximately one third of all the benign vascular lesions found in the gastrointestinal tract.

The frequent occurrence of these lesions, contrasted with the rare occurrence of symptoms, might lead one to consider them as mere pathological curiosities; however, 14 cases in which hemorrhage into the bowel or retroperitoneal space occurred have been cited in the literature. Three of the patients died.

The phlebectasia type of hemangioma generally involves long segments of the gastrointestinal tract. Consequently surgical extirpation is impossible unless a definite bleeding point which can be locally excised is demonstrated. One patient from the Mayo Clinic series with hematemesis and melena during the previous year underwent exploration and was found to have numerous lesions in the small intestine. In this case snake venom was given in decreasing amounts for the succeeding 4 years with no further gastrointestinal bleeding. Study and further evaluation of this method of treatment is necessary.

2. Cavernous hemangiomas of the simple polypoid type. The simple polypoid hemangiomas appear as single isolated cavernous lesions associated with the submucosal vascular plexus. They may enlarge and prolapse into the lumen of the associated hollow viscus and thereby cause ulceration, hemorrhage, and intestinal obstruction.

The general incidence of these lesions is much lower than that of the preceding group; however, a larger proportion of cases has been reported because of the tendency of the lesions to produce gastrointestinal symptoms which require treatment. There were records of 14 cases at the Mayo Clinic and reports of 36 cases were found in the literature; thus, these 50 cases represent 10 per

cent of all the benign vascular tumors located in the gastrointestinal tract.

Eighty per cent of the polypoid cavernous hemangiomas encountered in this review produced gastrointestinal hemorrhage or obstruction.

Surgical extirpation was possible in more than 46 per cent of the cases. Four patients (8%) died.

3 Cavernous hemangiomas of the diffuse expansive type. Cavernous hemangiomas in this subgroup are characterized by great variation in size, shape, and effect on the immediate substrate. Many of these tumors are found to involve from 20 to 30 cm. of the gastrointestinal tract in one contiguous segment. Their gross appearance in the peritoneal cavity is determined by the structures covered by the expansive lesion, whereas in the rectum they produce soft, compressible, nodular dark purple elevations under the mucosa.

Microscopic examination of sections through the periphery of these tumors reveals numerous dilated tortuous vessels as well as an abundance of smooth muscle and fibrous connective tissue stroma. One might therefore postulate the convergence of normal vascular structures in the antecedent history of these lesions. In other areas, however, the typical histopathologic pattern of cavernous hemangiomas is demonstrated with no evidence of smooth muscle or elastic fibers in the connective tissue septa.

Records of 40 diffuse cavernous lesions were found and 38, or 95 per cent, produced symptoms. Gastrointestinal bleeding was observed in 23 cases, while obstruction to the lumen of the bowel occurred in 14 others. The serious nature of these complications is emphasized by the fact that death occurred in 27 per cent of the cases.

Eighteen patients had diffuse cavernous hemangiomas in the small intestine. Five experienced severe gastrointestinal hemorrhage, while 5 others had symptoms from obstruction. Only 4 patients had both intestinal bleeding and obstruction. Resection of the tumor was possible in 8 cases, with 3 deaths. An exclusion type of operation was performed in 1 case, but the patient died of a severe hemorrhage from the remaining hemangioma.

The records of 20 patients with diffuse cavernous hemangiomas of the colon and rectum are summarized in Tables II and III. Seventy-five per cent of these lesions produced hemorrhage, while 25 per cent caused some degree of obstruction to the lumen of the bowel. Nine hemangiomas were excised whereas colostomy with injection treatment or roentgen therapy was utilized in 2 other cases. An over-all mortality rate of 45 per cent from these tumors was observed.

In the majority of patients with a large cavernous hemangioma of the rectum the onset of hemorrhage is noted soon after birth. Severe bleeding recurs until some adequate form of treatment is instituted or the patient may die of profound shock early in life. The natural tendency toward conservative forms of treatment for these so-called benign lesions must be carefully weighed against the very high morbidity and mortality rates associated with symptomatic treatment. In general, the prognosis is grave unless resection of the rectum with excision of the associated tumor is undertaken or some type of colostomy is combined with extensive roentgen therapy.

4. Cavernous hemangiomas of the multiple diffuse expansive type. Diffuse cavernous hemangiomas may occur simultaneously in separate organs or tissues throughout the body. Sixteen cases in which multiple lesions occurred were found in this review. Two of the patients had hemangiomas of the stomach and similar lesions on the surface of the body. In each of the 14 others 1 diffuse expansive hemangioma was located in either the colon or rectum while a second and rarely a third cavernous hemangioma involved adjacent viscera within the peritoneal cavity or was located on the surface of the body.

Fifteen, or 94 per cent, of the patients had severe rectal hemorrhages. Gross hematuria was present in 2 cases in which cavernous invasion of the urinary bladder occurred.

The treatment given these patients was individualized to fit the location of the tumor and the severity of the complications. Three died of severe exsanguinating hemorrhages while another died of peritonitis following resection of the colon with excision of the associated tumor. One patient was free of symptoms after a combined abdominoperineal resection for a cavernous hemangioma. Five patients continued with hemorrhage in spite of conservative treatment.

MALIGNANT VASCULAR TUMORS

In spite of the fact that benign vascular tumors are exceedingly common, their transitional forms and malignant counterparts are rarely seen. In an extensive review of the literature, Stout felt compelled to reject many of the lesions labeled with some name suggestive of a malignant vascular tumor. This was done because of inadequate histologic reports or because he considered that the illustrations and text described a tumor of some other kind. On the other hand Broders and many others (174, 233) have presented very detailed and carefully defined criteria for the classification of various malignant vascular neoplasms.

TABLE II.—PUBLISHED CASE REPORTS OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT ACCORDING TO TYPE

Telangiectata, Hereditary and Nonhereditary

Author year	Sex, age	Location	Remarks
Oaker (4) 1911	M 35	Lips, nose, stomach	Lesion 3 by 4 mm. Family history positive. Epistaxis, coffee-ground vomitus. Death
Libert 1913	M 45	Stomach	Coagulated small veins in stomach. Family history positive. Melena. Gastro- trostomy. No gross ulceration. No further bleeding
Newton 1919	F 79	Stomach, neck, chest	Family history questionable. Hematemesis and melena since childhood. Death from gastric hemorrhage
Newton 1920	M 32	Stomach, lips, face	Hematemesis and melena since childhood. Ligation of arterial supply to vascular area. No further bleeding for 5 years
Kessel 1921	M 52	Stomach, nose, lips	Possible telangiectata. Melena. Partial gastrectomy. Continued bleeding. Family history positive
Schuster 1927	F 62	Stomach, nose, pharynx	Recurrent gastric hemorrhages throughout life. Lesions found at autopsy. Family history positive
Rosenhaw 1929	M 44	Stomach, lips, tongue	Recurrent pharyngeal and gastrointestinal bleeding for years. Seen at gastrectomy
Watson and McCarthy 1940		Stomach, lips	Repeated hematemesis. Family history positive
Watson and McCarthy 1940		Stomach, pharynx	Death from gastric hemorrhage
Stellar 1922 (case)	F(?) 50(?)	Stomach, nose, tongue	Repeated gastrointestinal bleeding. Lesions found at autopsy. Family history, positive
Wilson 1940		Gastrointestinal	Gastrointestinal bleeding
Fox 1928	F 8	Nose, trunk, gastrointestinal	Epistaxis and gastrointestinal bleeding, 8 years
Hitchmann and Otraw 1945	M 49	Mouth, rectum	Hematemesis and melena. Family history positive
Richardson 1947		Nose, gastrointestinal	Gastrointestinal hemorrhages before onset of epistaxis
Barford 1948		Nose, gastrointestinal	Severe recurrent hematemesis, epistaxis, melena. Family history positive
Bucks 1948	M 30	Eyes, mouth, tongue, gastro- intestinal	Interruption appearance of lesions. Recurrent epistaxis and melena. No family history
Harper 1949		Gums, tongue, gastrointestinal	Recurrent bleeding from tongue, tarry stools. Family history positive
Newton 1950	M 30	Nose, gastrointestinal	Recurrent epistaxis and hematemesis. Family history positive
Fitz-Hugh 1	M 62	Nose, colon, rectum	Recurrent epistaxis and melena since childhood. Rectal biopsy positive
Fitz-Hugh 2	F	Nose, tongue, gastrointestinal	Recurrent epistaxis and melena
Gekhter (3) 1947 (case)		Stomach	positive
Orlows and Baker 1941	M 40	Nose, skin, gastrointestinal	seen for 20 years. Skin biopsy
Orlows and Baker 1941	F 30	Skin, nose, mouth, gastro- intestinal	since childhood. Multiple telangiectata
Orlows and Baker 1941	F 30	Nose, pharynx, gastrointestinal	Family history positive
Flad 1941		Macropharynx	no history

TABLE II.—PUBLISHED CASE REPORTS OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT ACCORDING TO TYPE—Continued

Capillary hemangioma, simplex or single

Author year	Sex, age	Location	Remarks
Vinson, Moore and Bowling 926	M 70	Esophagus	1
Lammers 1893	M	Stomach	Incidental finding at autopsy. No symptoms
Stocks 904-05	1 days	Cardia of stomach	Severe hematemesis and melena. Death
Eusterman and Sentry 921	F 50	Stomach	
Eusterman and Sentry 922	M 50	Stomach	
Eusterman and Sentry 923	M 67	Stomach	Reported by Lemon and by Judd and Rankin
Judd and Rankin 924	M 67	Stomach	Reported by Lemon and by Eusterman and Sentry
Judd and Rankin 925	F 52	Stomach	Reported by Eusterman and Sentry ¹
Judd and Rankin 1922	M 52	Stomach	Reported by Eusterman and Sentry
Sieboer 1923		Cardia of stomach	Resection of stomach
Eusterman and Balfour 925	F	Stomach	Reported by Eusterman and Sentry and by Judd and Rankin
Eusterman and Balfour 926	M 50	Stomach	Reported by Eusterman and Sentry
Glickson 942	M 40	Stomach	Lesion 1 by 1 cm. Found incidental to operation for stab wound
Carman 927	F	Stomach (prolapse into duodenum)	Reported by Eusterman and Sentry and by Judd and Rankin
Balfour and Headerson 929	F	Stomach	Reported by Eusterman and Sentry by Judd and Rankin and by Carman
Rankin and Newell 933	F 52	Stomach	Reported by Eusterman and Sentry by Judd and Rankin, by Carman and by Balfour and Headerson
Oberndorfer 1929	M 43	Upper part of small intestine	
Lichstein and Dietz 943	F 64	Ileum	"Angio-fibroma." Intestinal obstruction. Double intussusception, resection. No further symptoms
Weber 936	M 43	Cecum	Beginning invagination of ileocecal area. Resection
Fobes 938	F 53	Cecum	Fibrocapsillary lipoma, 4.5 by 4.5 cm. Pain, cramps and vomiting. Intussusception of cecum. Resection. Recovery
Sawyer 939	M 55	Sigmoid colon	Lesion 5 by 5 cm. Intestinal obstruction. M. lica. Mikulicz resection. Recovery
Edwards 908	F 48	Extraintestinal	Angiofibroma. Enlargement for years. Resection. Recovery
Forrester 920	F 50	Rectum, rectovaginal septum	Hemangioma. Tumor protruding at vulva, years. Rectovaginal fistula. Resection. Recovery

Mixed capillary and cavernous hemangioma

Morton and Burger 91	F 36	Stomach	Cavernous hemangioma. Endothelial proliferation
----------------------------	---------	---------	---

TABLE II.—PUBLISHED CASE REPORTS OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT ACCORDING TO TYPE—Continued
Mixed capillary and cavernous hemangioma—continued

Author year	Sex, Age	Location	Remarks
Labrousche 87	M 64	Duodenum	Erectile tumor. Capillary spaces and acinar dilatations. Recurrent hematemesis and melena. Death from massive hemorrhage
Mogre and Schrammer 934	M 58	Duodenum	Diffuse nodular hemangioma. Persistent chronic gastrointestinal hemorrhage. X-ray operation. Death
Sewall 912-1914	M 380	J jejunum	Hemangioma, thick-walled vessels and partly large spaces. Investigation. Excision. Recovery
Rusbyrd 1934	M 60	Jejunum	Hypertrophy of blood vessels and cellular infiltration. Anorexia, weight loss, increasing constipation, pain, vomiting, hematemesis, 6 months. Excision of loop of jejunum
Marchant 939	F 6	Jejunum	Small capillary and large vascular spaces (3 by 3 cm.). Intestinal obstruction. Death while in shock from bleeding and intramucosal polypoid tumor
Moschler 938	M	Appendix (cm in length)	Angiofibroma, all portions of the vascular system reproduced. Symptoms of acute appendicitis, torsion of tumor of appendix
Quain 1855	M	Rectum	Pedunculated, spongy vascular tumor. Half teaspoon of blood lost with each bowel movement. Excision. Recovery
Cavernous hemangioma, multiple phlebotomata type (small cavernous)			
Seamster 1866	F 76	Esophagus and rectum	Multiple small cavernous lesions in submucosa. No digestive symptoms. Death from infection of hand
Reemcke 908	M 53	Entire gastrointestinal tract	Schistosoma, communicating blood-filled cavities. Death from tuberculous meningitis. No known digestive symptoms
Dubois, Kaudon and France 914	F 19	Esophagus	Many endothelium-lined polypoid spaces. Hematemesis at 5 and melena at 10 years of age. Splenectomy. Artery of bleeding. Esophagotomy; biopsy and tuberculin of tumors. Well 1 year after treatment
Lié 879	M 86	Stomach and upper part of jejunum	Multiple hemangiomas. Death from gastric gangrene and hemorrhage
McClure and Ellis 930	F 30	Stomach, jejunum, liver, and spleen	Multiple hemangiomas (mm. to 35 mm.). Recurrent severe gastrointestinal bleeding, 10 years. Laparotomy. 1 case tumor. Operation. Death from hemorrhage from intestine
Marchant 1939	M 8	Stomach, jejunum, left kidney and adrenal	Multiple hemangiomas (3 by 3 cm.). Anemia, 8 years. Intramucosal of jejunum. Operation. Death
Okubo 1907	M 79	Small intestine	Multiple hemangiomas. No known gastrointestinal symptoms. Death from pneumonia
Ackerman 1937	M 8	Duodenum, jejunum, colon, gall bladder	Multiple cavernous hemangiomas. Anemia. Occult blood. Death from retroperitoneal rupture of duodenal hemangioma. No intestinal ulceration
Georgyev 1866	M 49	Body surface, small intestine	Multiple cavernous hemangiomas. Death from suffocation with enlarging cysts of parotid gland
Thierfelder 87	M 48	Small intestine	Cavernous hemangioma. No clinical symptoms. Death from trauma
Thierfelder 1873	M 43	Small intestine	Multiple hemangiomas. No clinical symptoms. Death from varicella
de Boyer 1877	M 6	Small intestine	Multiple hemangiomas. No clinical symptoms. Death from pneumonia. 1st hemangioma
Lié 879	M 53	Jejunum, colon, rectum	Multiple submucosal hemangiomas. No clinical symptoms. Death from cancer of colon
Lié 1879	M 65	Small intestine	Multiple hemangiomas. No gastrointestinal symptoms. Death from pulmonary tuberculosis
Ort 1880	M 63	Small intestine, colon	Multiple hemangiomas. No intestinal symptoms. Death from infection
Hertzen 1897-1899	M 48	Small intestine	Dilated veins, cavernous hemangioma. No intestinal symptoms. Death from mitral endocarditis
Mac Callum (1908)	M 54	Small intestine	Multiple hemangiomas. Alcoholic, vomited blood one time. Digestive disturbance for 6 months. Death from pneumonia
Moschler 19	M 5	J jejunum	Multiple hemangiomas. Death from carcinoma of esophagus
Moschler 1947	M 48	Small intestine	Multiple hemangiomas. Death from trauma. No intestinal symptoms

TABLE II.—PUBLISHED CASE REPORTS OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT ACCORDING TO TYPE—Continued

Cavernous hemangiomas, multiple phlebectasia type (small cavernous)—continued

Author year	Sex, age	Location	Remarks
Moeller 97	M 47	Small intestine	Multiple hemangiomas. Infectious diarrhea
Schmalzke 924	M 49	Small intestine	Multiple hemangiomas
Staemmler 924	M 67	Small intestine	Multiple hemangiomas. Death from carcinoma and syringoma of flexum
Staemmler 924	M 65	Jejunum	Multiple hemangiomas. No gastrointestinal symptoms
Saint 927		Small intestine	Multiple hemangiomas
Toepfer 928	no	Intestine	Multiple simple angiomas with capillary "ectasia." Also skin, mouth, submaxillary gland, thyroid, liver, lungs, urinary bladder involved.
Jaffé 929	F 20	Small intestine, sigmoid	Multiple blood-filled spaces. Death from acute suppurative condition and pyelitis. Also skin, thyroid, lungs involved
Rafford 93	M 54	J. junction	Numerous hemangiomas. Death from bronchopneumonia
Dudley 934	M 56	Small intestine studded	Multiple hemangiomas (5 by cm.). No symptoms six years after operation
Bullé and others 934	M 65	Small intestine, colon, rectum	Multiple hemangiomas. Gastrointestinal bleeding. Preoperative diagnosis of "ulcer." Seen with proctoscope
Bernsode, Hillebrand and Gemstone 935	F 55	Jejunum, sigmoid	Multiple hemangiomas. Many episodes of melena. N. resectable lesion found on exploration
Ackerman 937	M 64	Ileum, jejunum	Six cavernous hemangiomas. Seen at autopsy
Merchaat 939	M 64	J. junction	Multiple hemangiomas. No known gastrointestinal symptoms. Death from hypertensive heart disease
Spivovsky 94		Ileum	Multiple cavernous hemangiomas
Lille 879	M 56	Colon	Multiple hemangiomas. Death from infection in various organs
Neelsen 879	M 56	Colon	Multiple hemangiomas. Psychosis. Death
Moeller 97	M 54	Sigmoid, mesocolon	Multiple hemangiomas. Death from carcinoma of esophagus
Staemmler 924	M 78	Colon	Multiple hemangiomas
Tjomsen 93	M	Ascending colon	Multiple hemangiomas. Carcinoma, tuberculosis, and ileocecal invagination
Letter 933		Gastrointestinal tract	Multiple cavernous hemangiomas
Amundsen 938		Gastrointestinal tract	Multiple cavernous hemangiomas
Carnot 979	37	Esophagus	Cavernous hemangioma on pedicle. Two severe episodes of hematemesis in 6 months. Death from shock from hemorrhage of tumor
Cockle 93		Esophagus	
Hokitansky (rep) 855		Stomach	"Erectile" tumors. May have been attached by broad base
Judd and Rankin 9	F 5	Stomach	Reported by Echterman and Senty
Echterman and Senty 9	F 5	Stomach	Reported by Judd and Rankin
Echterman and Haller 935		Stomach	Reported by Judd and Rankin

TABLE II.—PUBLISHED CASE REPORTS OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT ACCORDING TO TYPE—Continued

Cavernous hemangioma, multiple phlebectasia type (small cavernous)

Author year	Sex, age	Location	Remarks
Gabriel 1917	M 9	Rectum	Rectal hemangioma. Recurrent rectal hemorrhage since 3 years of age. Resection N hemorrhage after months
Phillips (9) 1920	M 8	Anus	Erectile tumor. Rectal hemorrhages. Irritation made it tense and turgid. Ligation enough. Recovery
Gorham 1920		Anus	Erectile tumor*
Syme 1924	M 8	Anus	Vascular tumor by 4 inches. Soft red tumor present since birth. Recurrent severe hemorrhages. Ligation. Removal. Recovery
Rokhtansky (20) 1925		Colon, rectum	Mentioned a blood-vascular new growth in his pathology text
Paul 1925	F 60	Gastrointestinal tract	Intestinal obstruction. Tumor torn loose from bowel during violent purging. Hemorrhage. Recovery

Cavernous hemangioma, diffuse expansive type (single contiguous)

Kegaries 1923		Esophagus	Secular dilatations, hemangioma
Wakeley 1925	F 6	Liver; extrinsic pressure on esophagus	Increasing dysphagia, 5 years. Vomiting. Hemangioma the size of closed fist removed from liver with diathermy. Recovery
Morton and Burger 1941	M 36	Cardia of stomach	Lesion 8 1/2 by 1 cm. Epigastric pain, year. Gastroscopy: polypoid mass on lesser curvature. Operation: numerous large tortuous blood spaces. Resection not attempted
Beer 1943	F 9	Duodenojejunal junction	Lesion 26 by 1 1/2 inch. Increasing weakness, hematemesis, anemia, 5 years. Duodenojejunostomy with exclusion of bowel and cavernous hemangioma. Postoperative hemorrhage, death
Delbet 1900	F	Small intestine	Lesion 3 1/2 by 3 cm. Chronic, subacute intestinal obstruction, long duration. Resection. Death
Roedelius 1923	F 36	J junction	Lesion 8 cm. long. Recurrent attacks of abdominal pain. Resection. Recovery
Brown 1924	F 36	J junction	Lesion 5 by 5 inches. Recurrent abdominal pain, vomiting and distention, a few months. Resection. Death
Landsle 1925	F 5	Ileum	Lesion 8 cm. long. Symptoms simulating acute appendicitis. Resection. Recovery
Michalson 1927	F 120.	Ileum	Severe vomiting, bloody stools, and palpable mass. Resection. Death from peritonitis
Bessett 1930	M 33	Jejunum	Mucosal ulceration. Whole small intestine filled with blood at autopsy. Death from pulmonary tuberculosis
Kortshorn 1930	M 4	Small intestine	Lesion 3 cm. long. Intestinal bleeding. Resection. Recovery
Peyton 1935	M 25	Jejunum, ileum	Pale, weak, severe anemia since birth. Exploration. Postoperative high voltage roentgen ray. No hemorrhage for 8 months
Pierce 1940	F 40	Jejunum	Diffuse hemangioma. Bright red blood passed 3 days after birth. Weakness, tarry stools, anemia, 25 years. Three abdominal explorations. Resection. N further symptoms
Morrison and Donah 1941		J junction	Lesion 60 cm. Two explorations, negative. Diagnosis after extensive roentgenologic examination
White 1941	M 12	Ileum	Lesion 5 inches long. Abdominal distress and severe intestinal hemorrhage. Resection. Recovery
Stajano 1941	F 16	Jejunum mesentery	Did not involve gastrointestinal tract
Packard 1943	F 16	Ileum	Lesion 8 by 4 by 2 1/2 cm. Frequent episodes of nausea, vomiting, cramps, marked weakness, and dark stools. Resection. Recovery
Bole and Swan 1949	F 47	Appendix, cecum	Reported by Hunt
Kauffman 1949	M 31	Cecum	Hyperplastic tagline (8 by 8 cm.) Intestinal obstruction. Intussusception. Resection. Recovery
Hunt 1941	F 47	Appendix, caecum	Reported by Bole and Swan

*Clinical details given in Table 3.

TABLE II.—PUBLISHED CASE REPORTS OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT ACCORDING TO TYPE—Continued

Cavernous hemangioma, diffuse expansive type (single contiguous)

Author year	Sex, age	Location	Remarks
Stacy 08	F 41	Uterus, colon, rectum	Severe rectal hemorrhages. Sigmoidoscopy Laparotomy Death during shock
Dujarier and Topous Khan 190	M	Sigmoid, colon	Intermittent rectal hemorrhages, anemia, weight loss
Rainey 038		Colon para-aortic area	Recurrent attacks of bleeding and diarrhea throughout life. Death from typhoid-coccus septicaemia
Watson and McCarthy 040	116	Kidney colon	Same case as Dean and McCarthy given below
Dean and McCarthy 040	36	Right leg, sigmoid, colon	Cited by Watson and McCarthy
Gant 023 (cases)		Rectum	Hemorrhage from slightest trauma since infancy
Wilbert and Ransom 077	F 100	Buttocks, vagina, rectum	Defecation impossible since birth without enema. Rectal hemorrhages. Radium tubes and radon seeds applied and growth regressed
Esa 03	M	Scrotum, rectum, penis	Bleeding since infancy. Operation. Recovery
Bernsade and co-workers (16) 03	M 44	Perineum, scrotum, penis, rectum	Rectal hemorrhage all life. Vasconstrictor drugs and radium therapy. Operation refused
Bernsade and co-workers (16) 03	M 43	Perineum, scrotum, penis, rectum	Bleeding from rectum since 6 years of age. Symptomatic treatment
Bole and Nosebrook 038	M 28	Rectum, kidney	Death from hemorrhage from rectum
Bernsade and Bertillon 018	M 30	Anus, rectum, scrotum	Alternating constipation and diarrhea. Some bleeding from rectum

Hemangioma, details insufficient for classification

Bouchard 002	F	Esophagus	"Nevus. Alcoholic, cirrhosis, cutaneous nevus, death from hematemesis. Perhaps esophageal varices
Gelsen 1013	M	Esophagus or stomach	Vascular tumor. Increasing dysphagia, 12 months. Esophagoscopy Esophageal bougies and local application of radium gave an ultimate satisfactory result
Anschuetz and Koojetzky 1st 0		Stomach	Alleged hemangioma.
Elison <i>et al</i> 1036		Stomach	Listed on chart only
Gutmann <i>et al</i> 013	M 45	Stomach	Possible hemangioma. Severe hematemesis and melaena. Gastroenterostomy. Bleeding continued. Nervi of face and thorax
Geschickter 013		Stomach, small intestine, rectum	Listed on chart from Johns Hopkins Hospital
Mixson and Geschickter 036	M 53	Stomach	Pain, vomiting, weight loss, death from gastric cancer
Marshall 041	55	Stomach	Angiomatosis. Associated with hereditary phillitic capillaryitis
Wassner 1883	M 55	Duodenum	Tubercle-like, 7 by 2.5 cm. Vascular tumor continuous with another tumor which rested upon the pancreas compressing the common bile duct
Hartman (104) 1015		Deum	
Peterson 018 (cases)	M? 0, 17	Cecum	Angioma, infarction of cecum. Ileotransverse colectomy. Resection of cecum. Recovery

*Clinical details given in Table 1.

TABLE II.—PUBLISHED CASE REPORTS OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT ACCORDING TO TYPE—Continued

Hemangioma, details insufficient for classification

Author year	Sex, age	Location	Remarks
Carbondell Belzer 1930 (case)		Small intestine	Angiomas
Klein 1935		Appendix	Solitary hemangioma
Anderson 1943	M 3	Omentobasilar	Teleangiectasia. Intermitting rectal bleeding, source not known
Reichel and Sassaniler 1944	M 18	Colon or rectum	Seen at autopsy
Valerie 1944		Rectum	Angioma and angiomatosis
Duch and Jones 1945		Small intestine	Listed in chart of benign tumors
Carrara 1946		Esophagus	Tumor found at autopsy
Byrders 1953	F 75	Esophagus	
Chorevoff 0		Stomach	
Gerrill and Orrison 1915	F	Stomach	Extensive tumor. Mass and tenderness. Krukenberg, hematoma, pain, indigest. Re- section of tumor
Dahlgren 1914	M 44	Stomach	Hematomatous. Large firm non-tender epigastric mass. Tumor excised with piece of gastric wall
Lewis and Broders 1913	F 30	Stomach	Not reported in detail
Blahd et al 1913	F 80	Stomach	Lumen 3 by 1 cm. Vomiting, obstruction, and distention, 4 days. Hemostasis because of coagulation. Death
Wolfe et al 1911	F 5 mo	Small intestine, lungs, other viscera	Whispering respiration. Cyanosis since 7 weeks of age. Death
Magnuson 1914	F 60	J. jejunum	"Ulcerated hemangioleiomyoma, 3 by 6 cm. Anemia, lower abdominal pain, lev- els. Surgical removal but metastasis found in regional nodes. Bone and skin believed it was hemangioendothelioma
May 1910		Stomach	
Mac Callum () 1910		Small intestine	Recurrent nodules. Metastasis to liver
Smith and Broders 1913	F 69	Stomach	
Smith and Broders 1913	F 48	Rectum	

Endothelioma

Jorgensen 1913		Stomach	Lumen 15 by 20 by 8 cm. Dahlgren and Chorevoff refer to this as case of hemangio- endothelioma
Hansmann 1896	M 69	Stomach	
Erismann 1900	34	Stomach	Alcoholic with vomiting, pain, dyspepsia of 6 years duration. Operation
Scoblen 1900	M 18	Stomach	Dahlgren refers to this case as possible hemangioendothelioma
Oettinger 1903	M 37	Stomach	Ten years of epigastric distress. Epigastric fullness and vomiting, 3 years. Operation
Clemens 1902		Stomach	This case excluded by Jagger, Jorgensen, Dewart, and Dahlgren. It appears uncertain as to whether deals with an endothelioma

*Clinical details given in Table 3

TABLE II.—PUBLISHED CASE REPORTS OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT ACCORDING TO TYPE—Continued

Endothelioma			
Author year	Sex, age	Location	Remarks
Donath 900		Stomach	
Morris 0		Stomach	Posterior gastroenterostomy to relieve pyloric obstruction. Under roentgen therapy the growth "apparently disappeared entirely." Patient gained 30 pounds.
Bagger-Jørgensen 79		Stomach	
Fontana 918		Stomach	Lymphangioendothelioma
Ollander 920 (cases)		Stomach	
Baumbeck 930	M 60	Stomach	
d'Aragón 933		Cecum	Symptoms simulating acute appendicitis
Lehman 935		Intestine/liver	Diffuse thickening of the entire intestine with secondary growths in the liver
Kaposi's sarcoma			
Winters and Boggs 9	M 67	Esophagus, stomach, duodenum, small and large bowel	"Malignant degeneration of vascular hemangiomata. Hematomata. Death. Also skin, liver, spleen involved. Alleged by many authors to have been a case of Kaposi's sarcoma."
Kaposi 87		Bowel lesions	Commented on bloody diarrhea in his 1 serotherapy case
Semenow 1897 (cases)		Stomach, colon	Pancreas and kidney also involved
Mariani 900		Stomach, small intestine, colon	
Della F. Vera 0 (cases)		Stomach and intestines	Eight years' duration. Trachea and bronchi also involved
Dillard and Weckman 935	M 8	Stomach and intestines	Six year progressive appearance of cutaneous lesions. No known gastrointestinal symptoms. Neck, legs, urinary bladder involved
Kroneow 933	M 33	Stomach, duodenum, ileum, cecum, and rectum	First nodule appeared on toe. Progressive appearance for 5 years. Back, face, extremities involved. Death
Szymanski 94	M 6	Stomach, duodenum, entire small intestine	Lumps on extremities for years. Nausea and abdominal cramps. Death
Leberthal 930		Intestines, extremities	Mentioned visceral involvement. No details given
Grigorjew 974		Small intestine	Extremities also involved
Profil 918		Small and large bowel	Clinical disturbance of gastrointestinal tract before skin lesions noted
Agutter and Finkle 947		Ileum	Lesions of feet for 3 years. Roentgen therapy: progress of disease not altered
Bowman 933			Skin lesions present 6 years. Gastrointestinal hemorrhages, 3 years. Death
"Benign" metastasizing hemangioma			
Ullman 1896	F 40	Intestines, rectum	"Capillary angiomas. Purple lesions of face developed. Biopsy: "Cavernous angioma." Four years later onset of bronchial and gastric hemorrhages. Death
Staman 189	F 400.	Small intestines	Angioma simplex. Endothelial hyperplasia. Death during operation for attempted extirpation. Skin, lungs, cerebral cortex involved
Ullmann 900	F 49	Intestines	"Cavernous hemangioma. Death from infection. Skin, other internal organs involved
Konjetny 9	F 4	Intestines	"Histologic appearance of cavernous hemangioma. Lesions in the lung, liver and intestines considered metastatic. Death

TABLE II.—PUBLISHED CASE REPORTS OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT ACCORDING TO TYPE—Continued

Angiosarcoma			
Author year	Sex, age	Location	Remarks
Philipsen 1901		Stomach, appendix, colon	Thirty-four months duration Eye, nasopharynx, spleen, testicle also involved
Thies 1904	M 36	Stomach	Large abdominal tumor palpated Abdominal exploration of internal hemorrhage Death Spleen, liver lungs also involved
Berry () 1914	F 35	Stomach	Sarcomatous angiosarcoma Abdominal pain, few months Operation
Makshoff 1913	F 34	Stomach	Pain in right quadrant, anorexia, jaundice months Death Primary lesion in liver with metastases to lungs and stomach
Frelich and Cox 25	M 46	Intestines	Pain in right shoulder 6 months Biopsy Radiation therapy Died with extensive metastases to lungs, spleen, liver and intestines
Phillips and Rivers 1920	F 18	Stomach	Angiofibrosarcoma Discussion, section on pathologic diagnosis

There are few forms of new growth about whose nature there has been so much divergence of opinion as is evidenced in the literature on malignant vascular tumors.

Classification of these tumors which involve the gastrointestinal tract may be made into five main groups: endotheliomas, with no further descriptive terminology; hemangioendotheliomas; benign metastasizing hemangomas, considered by many pathologists as malignant Kaposi's sarcomas and angiosarcomas.

Endotheliomas In 1869 Golgi introduced the term endothelioma to describe a group of tumors which form endothelium-lined spaces. Soon after this original article was published a large number of tumors were classified under this title; however as the genesis of many epithelial purely sarcomatous, and mixed-cell types of tumor has been worked out, this terminology has been retained for only a few lesions.

This type includes those whose obvious morphologic features determine the true endothelial nature of the cells, and any tumor now classified as an "endothelioma" requires a certain cell type of mesenchymal origin, must be capable of forming intercellular mesenchymal fibrils, and must have the inherent growth characteristic of demonstrating an alveolar nature or rudimentary lumen-forming elements.

No malignant vascular lesions of the gastrointestinal tract are now classified solely under this heading at the Mayo Clinic; however a large group of tumors of historical and pathologic interest are thus described in the literature and will be reviewed in this and another section of the study.

Data on 61 malignant vascular tumors of the gastrointestinal tract have been collected in this

review. Fourteen of the lesions reported in the literature were termed "endothelioma." Twelve were located in the stomach; 1 was in the cecum, and 1 was vaguely described as occurring in the intestine and liver.

Two patients with endothelioma of the stomach experienced a sensation of epigastric pressure and fullness for from 6 to 10 years before pyloric obstruction developed.

A gastric resection was followed by complete relief of the symptoms in 2 cases, whereas in a third case the tumor was considered too extensive for removal and gastroenterostomy was undertaken to avoid further obstructive symptoms. The endothelioma in the third case allegedly disappeared after roentgen therapy.

An endothelioma of the cecum caused symptoms simulating acute appendicitis and was removed.

Perhaps the histopathologic classification of these tumors would be modified if the tumors were re-examined with more recent and rigid criteria; therefore any conclusions regarding methods of treatment and prognosis must necessarily be limited.

Hemangioendothelioma The majority of malignant tumors which form vascular tubes, which have endothelial cells in their basic stroma, and which demonstrate aggressive growth characteristics, including metastasis, were termed "hemangioendotheliomas" by Mallory in 1908.

Stout, in 1943 listed the modern theories of histogenesis and pathology which assist in the classification of hemangioendotheliomas.

In the gastrointestinal tract hemangioendotheliomas are usually situated in the submucosa, they are lobulated; they are accurately delimited with alternating soft and firm regions, and they some-

times present areas of degeneration. In the stomach and colon they tend to be pedunculated and may extend into the lumen for a distance of 2 or 3 cm.

The histopathologic features of these human angioendotheliomas include those of vascular tubes and sinuses lined by atypical fusiform and oval shaped endothelial cells which contain scattered mitotic figures together with occasional giant cells and a delicate fibrous framework which may be clarified by use of the Gomori reticulum stain. The highly anaplastic angioendotheliomas contain numerous mitotic figures and exhibit an extreme degree of atypical endothelial hyperplasia characterized by closely packed cords or masses of cells without evidence of capillary or sinus formation.

Most authors agree that metastatic lesions from angioendotheliomas occur first in the regional lymph nodes and because of this fact, together with the definite tendency toward encapsulation, there is increased opportunity for their complete surgical eradication with a more favorable prognosis.

Incidence and distribution. The vascular lesions classified in this group represented 35 per cent of all malignant tumors encountered in this review. They were found in every segment of the gastrointestinal tract although a large majority appeared in the stomach and small intestine.

Symptomatology, treatment, and prognosis. The symptoms produced by angioendotheliomas, like those of the other vascular tumors which involve the gastrointestinal tract, depend to a large extent on the location of the lesion. The treatment as well as the prognosis is also conditioned by the location and by the grade of malignancy.

The angioendotheliomas involving the esophagus produced severe dysphagia, progressive malnutrition, and death following perforation and mediastinitis.

The average age of the 9 patients with angioendotheliomas of the stomach was 48 years. Four patients were under 32 years of age.

Anorexia, weight loss and vague symptoms of so-called indigestion were noted in 6 cases while gastric bleeding, severe anemia and associated progressive weakness were observed in 8 others. The average duration of symptoms was more than 3 years in 6 of the cases while in the other 3 cases the patients were examined before their symptoms had been present for a year.

Local excision of the tumor was possible in 6 cases, while a partial gastrectomy was undertaken in 2 others.

Six patients were followed up carefully and 3 of these were free of symptoms more than 20 years after removal of the tumor. The fourth patient was living and well 4 years after surgical treatment, while the fifth patient died as the result of another disease 7 years after removal of the gastric lesion.

In 4 patients with angioendothelioma of the duodenum or small intestine, signs and symptoms of obstruction developed while in 3 bleeding from ulcerations on the mucosal surface of their tumor occurred.

In only 4 of the 6 cases of angioendothelioma of the duodenum or small intestine was exploration performed and the lesion excised. One patient died of surgical complications and 2 patients were not followed up over a long period of time.

Rectal swelling, tenesmus and bleeding were observed in 2 patients with angioendotheliomas located just above the anal margin. The first patient was living and well with no rectal complaints 13 years after local excision and radium therapy for a low grade lesion (Broders' classification). The second patient was found to have fluid in the thorax from a metastatic grade 3 angioendothelioma of the rectum. He failed rapidly in spite of local radium packs applied to the rectal lesions and extensive roentgen therapy over the chest.

Many of the angioendotheliomas appear in young adults who may give a history of relatively long duration of symptoms. The prognosis is excellent for patients who have low grade lesions which are surgically excised and followed by extensive radiation therapy. The higher grade lesions metastasize early to both local and distant parts of the body and are not cured after removal of the primary growth or with extensive adjunctive radiation therapy.

Benign metastasizing hemangiomas. Another group of vascular tumors which have given rise to a considerable amount of discussion in the literature are the so-called "benign metastasizing hemangiomas." They are characterized by extensive metastasis in spite of a seemingly benign histologic pattern. The existence of such a group has an intimate bearing on the question of the essential similarity of all benign and malignant processes. Some authors have attempted to discredit altogether the criteria by which these lesions are classified as benign.

Pathogenesis. Lubarsch raised the question whether there is a primary growth in these neoplasms, or whether there are independent growths with multiple foci of origin.

TABLE III.—ABRIDGED REPORT OF 106 CASES OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT BY TYPE

Capillary hemangiomas, simplex or single

Case	Sex, age	Location	Remarks
1	M 70	Esophagus	Lesion by 5 cm. Increasing dysphagia and weight loss for 6 months. Esophagoscopy biopsy and radium implantation. Death 18 months from hemangioma obstructing esophagus
2	M 30	Stomach	Lesion by 3 by 5 cm. Weakness, belching after meals, and recurrent vomiting, 12 months. Oesophagomy local excision of hemangioma. No further symptoms, 12 years
3	M 53	Sigmoid, colon	Lesion by 1 by 1 cm. History of ulcerative colitis. No recurrence, 3 years. Proctoscopy excision of hemangioma, base fulgurized. No further symptoms, 13 years
4	M 67	Cecum	Lesion by 1.5 by 1 cm. Death from hypertension, arteriosclerosis, and hemiplegia. Hemangioma incidental finding at autopsy
5	M 44	Rectum	Lesion by 1.5 by 1 cm. Swelling of pressure in rectum, 10 months. Hemangioma cm. above dentate line excised with clamp and cautery. No recurrence, 9 years
6	F 48	Rectum	Lesion by 3 by 1 cm. Fell on picket fence, 14 lateral perianal and pararectal area at 6 years of age. Rectal tenosus developed at 27 years of age. Excision of bluish colored rectal growth. No recurrence, 3 years

Mixed capillary and cavernous hemangiomas

7	M 8	Esophagus, jejunum	Lesion by 3 by 1 cm. Incidental finding at autopsy. Death from complications following transurethral prostatic resection
8	M 67	Stomach	Lesion 6 by 3 by 5 cm. ulceration of mucosa. Pain and sense of fullness in epigastrium, 12 pound weight loss, dark stools, 4 months. Sleeve resection of stomach. Death 4 years later from chronic nephritis. No recurrence of hemangioma
9	M 63	Stomach	Lesion by 3 by 1 cm. Anorexia and 30 pound weight loss, 6 months. Transgastric exploration, partial Pylor gastric resection. No symptoms or roentgenographic evidence of recurrence, 6 years
10	M 59	J. jejunum	Lesion 3.5 by 2.5 by 1 cm. Movable, tender firm mass palpated in abdomen. Local excision of hemangioma at jejunoenterostomy border
11	M 74	Jejunum	Lesion 5 by 1 cm. Incidental finding at autopsy. Death from myocardial infarction 7 days after suprapubic prostatectomy
12	M 55	Jejunum	Lesion 3 by 1 by 5 cm. Three severe gastrointestinal hemorrhages with no other symptoms. years. Roentgenogram of small intestine; tumor observed. Resection. No further hemorrhage, 4 years
13	F 39	Ileum	Lesion by 1 by 1 cm. Adhesive band between cecum and (absorption tube produced obstruction of ileum. Hemangioma found in resected ileum. No further gastrointestinal symptoms, 13 years
14	F 16	Appendix	Lesion 0.5 by 1 cm. Recurrent right lower abdominal pain, years. Appendix retrocolic and covered with adhesions. Appendectomy and left oophorectomy. No further symptoms
15	F 30	Rectum	Lesion 3 by 1 by 1 cm. Swelling of pressure and swelling in perineum, 6 years. Excision of hemangioma in rectum and rectovaginal septum. No recurrence, 3 years
16	M 46	Rectum	Lesion by 0.5 by 1 cm. Recurrent pain from hemorrhoids and sensation of obstruction to rectal outlet, 7 years. Hemorrhoidectomy and local excision of polymorphous hemangioma. No further rectal complaints, 4 years

Cavernous hemangiomas, multiple phlebotomata (type small cavernous)

17	M 57	Esophagus, small intestine	Incidental finding at autopsy. Death from pneumonia, central nervous system syphilis and hypertension
18	M 64	Esophagus, small intestine, colon	Incidental finding at autopsy. Death from pneumonia, complication of suprapubic prostatectomy
19	M 60	Esophagus, small intestine	Incidental finding at autopsy. Death from myocardial infarction
20	M 30	Esophagus, stomach, small intestine, colon	Incidental finding at autopsy. Death from streptococcal septicemia secondary to carbuncle of neck
21	M 73	Esophagus, Duodenum, colon	Incidental finding at autopsy. Death from unresolved lobar pneumonia. Left auricular appendage of heart contained hemangioma
22	M 77	Esophagus, small intestine	Incidental finding at autopsy. Death from hypertension, coronary atherosclerosis, and infarction of left ventricle
23	M 73	Duodenum, small intestine	Incidental finding at autopsy. Death 10 months after prostatectomy of pulmonary embolism
24	M 43	Duodenum, small intestine	Incidental finding at autopsy. Death from syphilitic arthritis
25	M 36	Duodenum, small intestine	Incidental finding at autopsy. Combined abdominopelvic resection for adenocarcinoma of rectum. Death from generalized peritonitis
26	M 60	Duodenum, small intestine	Incidental finding at autopsy. Death from prostatic hypertrophy, pyelonephritis, and trauma

TABLE III.—ABRIDGED REPORT OF 106 CASES OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT BY TYPE—Continued

Cavernous hemangioma, multiple phlebotomized type (small cavernous)

Case	Sex, age	Location	Remarks
27	M 64	Duodenum, small intestine, colon	Incidental finding at autopsy Death from hypertension and uremia
28	M 74	Duodenum, small intestine	Incidental finding at autopsy Partial gastrectomy for ulcerating adenocarcinoma. Death from postoperative pneumonia and peritonitis
29	M 71	Duodenum, small intestine	Incidental finding at autopsy Death from multiple myeloma and lobar pneumonia
30	M 73	Duodenum, small intestine	Incidental finding at autopsy Death from aortic endocarditis and dilatation of left ventricle
31	M 43	Jejunum	Hematemesis, melena, epigastric pain, years. Posterior gastroenterostomy for duodenal ulcer. Hemangioma seen during surgical exploration. No further symptoms, 23 years
32	F 68	Small intestine	Incidental finding at autopsy Death from pulmonary embolism 8 days after radical amputation of left breast for adenocarcinoma
33	M 63	Small intestine	Incidental finding at autopsy Death from hemorrhage from duodenal ulcer
34	M 78	Small intestine	Incidental finding at autopsy Death from carcinoma of prostate and pulmonary metastasis
35	M 60	Small intestine	Incidental finding at autopsy Partial gastrectomy for adenocarcinoma. Death from duodenal fistula and peritonitis 6 days after operation
36	M 41	Small intestine	Incidental finding at autopsy Death from general peritonitis and pneumonia 9 days after antrum excision of gastric ulcer and posterior gastroenterostomy
37	M 63	Small intestine	Incidental finding at autopsy Death from generalized arteriosclerosis angina pectoris, and coronary sclerosis
38	M 6	Small intestine	Incidental finding at autopsy Death from carcinoma of pancreas
39	M 46	Small intestine	Incidental finding at autopsy Death 7 days after suprapubic cystostomy and insertion of radium needles for carcinoma of bladder. Bronchopneumonia and empyema
40	M 45	Small intestine	Incidental finding at autopsy Death from pulmonary abscess 3 months after tooth extraction
41	M 69	Small intestine	Incidental finding at autopsy Death from septicemia and multiple lung abscesses 18 days after suprapubic cystostomy and diathermy for squamous cell epithelioma of bladder
42	M 56	J. jejunum, ileum, rectum	Incidental findings at autopsy Death from bronchopneumonia and empyema
43	M 55	J. jejunum, ileum	Incidental findings at autopsy Death from peritonitis 9 days after resection for obstructive adenocarcinoma in the rectosigmoid
44	M 60	Jejunum, ileum	Incidental finding at autopsy Death from bilateral pulmonary edema and bronchopneumonia 8 days after right pelvicotomy. Bilateral sigmoid calculi
45	M 65	Small intestine, colon	Incidental finding at autopsy Death from pericardial aneurysm and fatty changes in myocardium
46	M 47	J. jejunum	Incidental finding at autopsy Death from local peritonitis 5 weeks after resection for obstructive adenocarcinoma of transverse colon
47	M 64	Small intestine	Incidental finding at autopsy Death from adenocarcinoma of stomach with metastasis to liver
48	M 70	Small intestine	Incidental finding at autopsy Death from severe dysphagia and bronchopneumonia after ingestion of "lysol"
49	M 64	Stomach, duodenum, small intestine	Incidental finding at autopsy Death from coronary occlusion and infarction of left ventricle
50	M 68	Small intestine	Incidental finding at autopsy Death from adenocarcinoma of rectum and perforation of duodenal ulcer
51	M 66	Small intestine	Incidental findings at autopsy Death from coronary sclerosis and infarction of left ventricle
52	M 53	Small intestine	Incidental finding at autopsy Death from cerebrovascular accident 7 days after transurethral prostatic resection
53	M 60	Small intestine	Incidental finding at autopsy Death from hypertension and cardiac decompensation
54	F 49	Small intestine	Incidental finding at autopsy Death from metastasis from adenocarcinoma of right breast

TABLE III—ABRIDGED REPORT OF 106 CASES OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT BY TYPE—Continued

Cavernous hemangioma, multiple phlebotic type (small cavernous)

Case	Sex, age	Location	Remarks
33	M 41	Small intestine	Incidental finding at autopsy Death from tuberculous meningitis
36	F 54	Small intestine	Incidental finding at autopsy Death from Korsakoff's psychosis and barbiturate poisoning
37	M 64	Duodenum	Incidental finding at autopsy Death from perforated gastric ulcer and peritonitis
38	M 47	Small intestine, colon, rectum	Incidental finding at autopsy Death from multiple brain abscesses and acute cerebrosplenic meningitis
39	M 69	Jejunum	Incidental finding at autopsy Death from coronary sclerosis and infarction of the left ventricle
40	M 73	Jejunum	Incidental finding at autopsy Death from psychosis and multiple infarcts of basal nuclei of midbrain
41	M 6	Jejunum, ileum	Incidental finding at autopsy Death from chronic asthmatic bronchitis and pulmonary emphysema
42	M 6	Small intestine	Incidental finding at autopsy Death from myocardial degeneration and peritonitis
51	F 43	Small intestine	Hematemesis and melena with associated syncope 3 years Diagnostic procedures did not reveal any lesion in gastrointestinal tract or blood dyscrasia Abdominal exploration and duodenostomy revealed only hemangiomas Small vessels given as decreasing amounts for 4 years with no return of hemorrhage
54	M 39	Small intestine	Recurrent tarry stools, 1 year Cholelithiasis and cholelithiasis No cause for melena observed except vascular tumors Death from acute yellow atrophy of liver in 4 months
55	M 60	Small intestine	Weight loss and weakness, 10 months Tarry stools, 10 days Hemangiomas observed during abdominal exploration and repair of paraesophageal diaphragmatic hernia No further melena, 7 years
56	M 6	Small intestine	Incidental finding at autopsy Death from hypertrophic pseudomembranous cystitis and colitis
57	M 7	Small intestine	Incidental finding at autopsy Death from cerebral arteriosclerosis and infarction of brain
58	F 39	Small intestine	Recurrent abdominal cramps and blood in stool 7 weeks Abdominal exploration during which inoperable small hemangiomas were observed throughout the small intestine Extensive melena observed post mortem Evidence of further chronic blood loss, 7 years
60	F 66	Jejunum	Incidental finding at autopsy Death from pneumonia following amputation of right breast for adenocarcinoma

Cavernous hemangioma, simple polypoid type

70	M 6	Esophagus	Lesion by 1 by 1 cm Increasing dysphagia and 5 pound weight loss, 6 months Esophagoscopy For biopsy cavernous hemangioma Second biopsy tissue similar to first biopsy as well as adenocarcinoma grade Radon tube therapy Death in 6 months
71	M 34	Stomach	Lesion by 8 by 1 cm Hematemesis, epigastric tenderness, and vague gastroesophageal distress, 1 year Partial gastrectomy for tumor protruding into duodenum Excellent health, 7 years
72	F 37	Duodenum	Lesion 3 by 4 by 1 cm Four episodes of nausea, hematemesis, melena, vertigo, and weakness, 7 years Erosion of pyloric sphincter anterior wall of duodenum and hemangioma No gastrointestinal symptoms, 7 years
73	F 73	Duodenum	Lesion 1 by 7 cm. Incidental finding at autopsy Death from cerebrovascular accident
	M 71	Ileum	Lesion 1 by 1 cm. Incidental finding at autopsy Death from chronic lymphatic leukemia
74	M 58	Jejunum	Lesion by 1 by 1 cm. Incidental finding at autopsy Death from hypertension arteriosclerosis, hypertrophy of prostate, and typhoid
75	M 7	Jejunum	Lesion 1 by 1 by 1 cm. Incidental finding at autopsy Death from emphysema 5 days after partial duodenectomy for bleeding duodenal ulcer
77	M 34	Ileum	Lesion by 1 by 1 cm. Incidental finding during operation for removal of granulomatous ulcer of cecum
78	M 34	Jejunum	Lesion by 1 by 1 cm. Incidental finding at autopsy Death from peritonitis 30 days after resection for obstructive adenocarcinoma of the transverse colon
79	F 30	Jejunum	Lesion 4 by 1 cm. Incidental finding at autopsy Death from cardiac decompression
80	F 66	Jejunum	Lesion 8 by 1 cm. Incidental finding at autopsy Death from primary carcinoma of the gall bladder

TABLE III.—ABRIDGED REPORT OF 106 CASES OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT BY TYPE—Continued

Cavernous hemangiomas, simple polypoid type

Case	Sex, age	Location	Remarks
8	M 63	Blenn	Lesion 1 by 1.5 cm. Incidental finding at autopsy. Death from hypernephroma of left kidney
9	F 50	Appendix	Lesion 6 by 6 mm. Incidental finding in appendix which was removed at same time as cholecystectomy for gangrenous cholecystitis
83	F 53	Sigmoid	Lesion 1 by 1 cm. Incidental finding at autopsy. Death from senile psychosis
84	M 26	Sigmoid	Lesion 5 by 3 cm. Extensive cavernous hemangioma of peric. scrotum, and perineal margin since birth. Local radium applications, 1 year of age. Two severe rectal hemorrhages (1 re years of age); a bleeding to mor was allegedly removed from rectum. Return of bright red blood on surface of each stool, 6 months. Weakness and anemia with no pain or cramps. Transcrotal excision of hemangioma. Third hemangioma palpated in right lobe of liver. N further bleeding, 1 year

Cavernous hemangiomas, diffuse expansive type (single contiguous)

85	F 50	J junction	Lesion 7 by 7 by 3 cm. Recurrent symptoms and signs of subacute intestinal obstruction together with abdominal mass, 1 year. Resection of 5 cm. of jejunum and contiguous hemangioma. N further symptoms, 4 years
86	M 33	Entire small intestine, colon, rectum	Recurrent severe intestinal hemorrhages requiring 5 blood transfusions, 9 years. Partial gastrectomy done elsewhere with return of hemorrhage. Ileotransverse colostomy, resection of 3 feet of ileum and right colon done elsewhere with return of hemorrhage. Abdominal exploration revealed entire small and large intestine covered with cavernous hemangioma. Patient could not have survived extensive resection necessary to remove hemangioma. Recurrent hemorrhages, 3 years
87	F 47	Cecum, appendix	A diffuse cavernous hemangioma which involved the entire cecum and appendix was observed during cholecystectomy for cholecystitis and cholelithiasis. No gastrointestinal bleeding in 8 year interval since operation
88	F 7	Sigmoid, rectum, bladder	Recurrent hemorrhages from rectum and bladder beginning 16 months after birth. Death from severe rectal hemorrhage in spite of local packing and supportive therapy
89	F 48	Colon	Lesion 4 by 5 by 4 cm. Recurrent abdominal cramps, increasing constipation, persistent tender mass in left lower quadrant, 6 years. Blood coating surface of stool 4 months. Cecostomy followed by first and second stage Milesian resection. Living and well 1 year after operation

Cavernous hemangiomas, multiple diffuse type (noncontiguous)

90	M 18	Sigmoid, rectum, kidney	Constipation since birth. Alternating constipation and diarrhea, pain in rectum, blood / stools, 1 year of age. Three episodes of gross hematuria. Roentgen therapy on basis of possible lymphoid hyperplasia. Returned 1 year later with extreme weakness, pallor and anemia from severe rectal hemorrhages. Transfusions. Radium pack. Shock and death from hemorrhage
91	F 24	Sigmoid, rectum, bladder, labia, leg	Recurrent hematuria, rectal hemorrhages and swelling of left leg since infancy. Suprapubic exploration and coagulation of bleeding points during episodes of severe hematuria. Rectum, sigmoid, and bladder extensively involved with cavernous hemangioma. Rectal and urinary hemorrhages continued for 3 years
92	M 33	Colon, liver	Lesion 4 by 1 cm. Incidental finding at autopsy. Death from metastatic adenocarcinoma from the rectum 1 year after combined abdominoparietal resection

Hemangioendothelioma

93	F 76	Esophagus, lower third	Grade 1 lesion 1 by 1 cm. Fullness in throat and esophagus without dysphagia or hoarseness, 7 years. Progressive dysphagia and chest pain, 6 weeks. Radiography. Biopsy and dilatation with No. 41 F bougie. Minimal roentgen therapy through two portals. Death 11 months
94	M 43	Stomach	Grade 1 lesion 4.5 by 4 by 3 cm. Epigastric pain and soreness relieved by alkalies, 8 years. Knife excision of ulcer crater and posterior gastrectomy. Free of symptoms, 5 years. Returned with dyspepsia on curries, weakness and secondary anemia, 4 years. "V" resection of lesser curvature and tumor. Death 7 years later from cerebrovascular accident. N recurrence of tumor
95	F 5	Stomach	Grade 1 lesion 1 by 1 cm. Indigestion for 4 years. Free of symptoms, 1 year. Constant midepigastric soreness not relieved by food or alkalies, 1 year. Severe hematemesis, anemia, and so pound loss of weight, 4 months. Gastrectomy with knife excision of tumor and surrounding gastric mucosa. No further gastrointestinal symptoms, 30 years
96	M 59	Stomach	Grade 1 lesion 4 by 3 by 1 cm. Weakness, weight loss, and tarry stools, 1 year. Free of symptoms, 9 years. Return of tarry stools and midepigastric pain, 4 months. Knife excision of tumor and posterior gastrectomy. No further gastrointestinal symptoms, 1 year
97	F 3	Stomach	Grade 1 lesion 4 by 3 by 3 cm. Weakness, tarry stools, and anemia, 1 month. Free of symptoms for 3 years. Recurrent episodes of anemia, 1 month. Freely movable tender epigastric mass. Gastric resection (posterior Polya). Excellent health, 22 years after operation
98	M 15	Stomach	Grade 1 lesion 7 by 6 by 6 cm. Severe hematemesis and melena, 3 months. Gastric resection (posterior Polya). Postoperative coagulation therapy. Death from metastasis, 6 years after operation
99	M	Stomach	Grade 1 lesion 7 by 6 cm. Tarry stools, 1 month. N symptoms for 1 year. Return of tarry stools and epigastric pain, 1 week. Abdominal exploration and biopsy done elsewhere. Patient refused further operation. Advised to have roentgen therapy 1 hour. Could not be located 1 year later

*Broders classification.

TABLE III.—ABRIDGED REPORT OF 106 CASES OF VASCULAR LESIONS OF THE GASTROINTESTINAL TRACT BY TYPE—Continued

Hemangiomas of the Gastrointestinal Tract			
Case	Sex, Age	Location	Remarks
100	M 30	Stomach	Grade lesion 4 by 4 by 1 cm. Freely movable abdominal mass 6 months. Tumor detached from posterior wall of pyloric antrum. Postoperative roentgen therapy. No evidence of recurrence 4 years after operation.
101	F	Duodenum	Grade lesion 5 by 2 by 1 cm. Loading with any dietary indiscretion. years. Cramp-like abdominal pain. Transabdominal excision of tumor. No evidence of recurrence, 4 years after operation.
102	M 59	Terminal ileum, mesentery	Grade lesion 4 by 4 by 3 cm. Recurrent lower abdominal pain, dark stools and 3 pound weight loss, months. Tumor mass in right lower part of abdomen. Two-stage (transverse colectomy and resection of right part of colon. Malignant disease of postoperative roentgen rays. Death from metastasis, 14 months after operation.
103	M 33	Blow	Grade lesion. Appendectomy and ileocectomy done elsewhere for "Ulcer." Return of abdominal pain and diarrhea in 1 month. Abdominal exploration and biopsy of nodular lymphatic, distal ileum, and peritoneum. Many atypical endothelial cells separated from lymphatics. Extensive roentgen therapy to chest and abdomen. Returned 3 years later with no evidence of abdominal mass, nausea, or hydrothorax.
104	M	Appendix	Grade lesion 8 by 8 by 6 cm. Recurrent upper abdominal pain, dark stools, weakness, 6 months. Abdominal exploration demonstrated no cause for intestinal bleeding. Small duodenogastric hernia. Appendicectomy. Death at home during convalescence. years after abdominal operation.
105	F 69	Rectum	Grade lesion 10 by 10 cm. Rectal transection. Sigmoideoscopic examination did not reveal any lesion six years later. Patient complained of painless rectal prolapse which progressed through 3 stages. Kaposi's tumor, non dilated, quiescent and area ruptured (see case 106) removed. Tumor banded and thirty radium hours of radium applied to breaking wound. No return of tumor. 3 years after operation.
106	F 37	Rectum	Grade lesion 5 by 5 by 1 cm. Bleeding with defecation, rectal transection, riboflavin stools, pain, anorexia, weight loss, persistent cough, 6 weeks. Examination revealed encapsulated arteriole and adenoma-like tumor with hyperplasia and an infiltrating lesion in the lower third of the rectum. Superficial radium applied to tumor, roentgen therapy to chest. Patient failed rapidly 3 months. Death.

Review classification

Robinson and Castleman, in 1936 stated that there were only 4 apparently authentic cases of this condition which had been reported respectively by Borrmann in 1907, Shennan in 1914, Ewing in 1919, and by Geschickter and Keasbey in 1935. Robinson and Castleman added 1 similar case of their own and separated the cases of Wright, Hall, and others into a group they called "metastasizing hemangiosarcomas." They also called another group "malignant," which was characterized by occurrence in children, a local invasive tendency, hemorrhage, and death.

Borrmann in discussing his case expressed the opinion that the presence of metastasis could no more be used to determine definitely the benign or malignant character of the process than could, for example, the absence of a capsule, rapid growth or invasiveness, which are not exclusively benign or malignant properties. Shennan wondered whether the histologic, rather than the clinical criteria were not at fault. Ewing considered the "benign metastasizing" angiosarcoma a borderline entity and described it as possessing certain peculiar features of malignancy. Jaffe expressed the thought that, because of their infiltrative growth and stroma of undifferentiated mesenchyme these lesions cannot be considered histologically benign. Stout, in 1943 reviewed all the reports on cases of "benign metastasizing hemangioma" and included the report of a detailed examination of Robinson

and Castleman's slides. His final conclusion was that they all show atypical endothelial and very free vascular anastomosis which definitely bring them into the class of hemangioblastomas.

In only 4 cases of "benign metastasizing hemangioma" in the literature was involvement of the gastrointestinal tract proved by biopsy. A summary of the data in these cases is given in Table II. These 4 vascular tumors involving the gastrointestinal tract might well be classified as hemangioblastomas if we could review the histopathologic details and include modern concepts of metaplasia, atypical mitotic figures, and evidence of invasion. On the other hand, one cannot help but feel that the existence of multiple primary benign hemangiomas rather than a metastasizing process could explain the origin and distribution of these lesions.

Kaposi's sarcoma. In 1872 an Austrian dermatologist Kaposi, described the lesions now generally called "Kaposi's sarcoma." He named it "idiopathic multiple pigmented sarcoma." In 1894 he changed the designation to "sarcoma idiopathic multiplex hemorrhagicum."

The early pathologists were uncertain as to whether this was an inflammatory or a neoplastic process. Some still believe that the tumor is implanted on an inflammatory base whereas most authors now feel that the process is a neoplasm of low grade malignancy.

More recent authors (48, 49, 66, 236) have attempted to reclassify the disease according to their theories as to its cell origin. Since the tumor contains blood vascular elements or cavernous blood filled spaces, and since many pathologists consider certain of its histopathologic features to be identical with those designated as "hemangioendothelioma," it will be considered in the same general group with other malignant vascular lesions which are found to involve the gastrointestinal tract.

The disease has a tendency to develop first on the extremities as a unilateral lesion, to become bilaterally symmetrical, and then to progress to a generalized condition involving most often the gastrointestinal tract. It appears to be especially prevalent in men of Italian or Gallican birth but, as Doerffels pointed out, there appears to be a geographic rather than a racial distribution since the vast majority of cases originate in Russia, Poland and Northern Italy.

Histopathology The histopathology of this lesion has been variously interpreted as being that of a sarcoma arising in angiomata of the skin, proliferation of the interstitial connective tissue and endothelium, a disturbance of the 'monocytogenic' function of the reticuloendothelial system, hemangioendothelioma and malignant proliferation of the perithelial cells, and, recently several cases of leucocytic dyscrasia have been mentioned in connection with this disease. Various histopathologic features may be observed in different lesions of the same individual and this may account for many of the varied histogenic interpretations.

Any cell type classification must explain how vascular channels predominate in some areas, fibrous tissues in others, and endothelial hyperplasia in most microscopic fields.

Choussier and Ramsey (49) in 1940, circumvented the problem of multicellularity by suggesting that all of the various types might arise from the reticuloendothelial system.

The cellular arrangement of the older lesions resembles that of a low grade hemangioendothelioma, and many pathologists consider this tumor as an unusual representative of this group. The apparent male sex linked character of this lesion is, however different from that of the general group of hemangioendotheliomas, in which the incidence is about the same in both males and females. In this connection it is interesting to note that in 365 cases of Kaposi's sarcoma reviewed by Doerffels, all but 21 patients were males.

The most striking feature exemplified by the pathologic anatomy of Kaposi's sarcoma is that

the same changes occur in the viscera as in the skin, this fact, together with simultaneous involvement, points to the possibility that the internal lesions are independent in origin and not truly metastatic. Paolini reported a case in which clinical symptoms appeared in the gastrointestinal tract before lesions could be found in the skin.

Incidence and distribution Becker and Thatcher in 1938, found reports of 440 cases in the literature. Twenty-six cases of Kaposi's sarcoma have been proved by clinical history and biopsy of skin lesions at the Mayo Clinic. Four of the patients had vague gastrointestinal symptoms and 2 others had previously had gastric resections before coming to the clinic. In only 1 case was a record of gastrointestinal bleeding noted in the history.

Fourteen cases in which specific mention was made of the presence of Kaposi's lesions in the gastrointestinal tract at autopsy have been reported in the literature.

The complete gastrointestinal tract is involved in many of the cases.

Symptoms, treatment, and prognosis. A review of the gastrointestinal symptoms produced by these lesions in the 14 cases referred to in a preceding sentence reveals that 9 reports made no mention of intestinal symptoms however 1 patient had severe hematemesis, 2 patients had tarry stools, 2 mentioned gastrointestinal disturbances, including nausea and vomiting while 1 patient had no known intestinal disturbance during life.

Two commonly accepted forms of treatment are, first, roentgen therapy and, second, administration of a solution of potassium arsenate (U.S.P.) by mouth, or of sodium arsenate by injection. Neither of these methods of therapy has prevented a fatal termination of the disease.

Angiosarcoma The sarcomas may be defined as malignant tumors composed of cells of the connective tissue type. A more descriptive term such as 'angiosarcoma' indicates the dominant histopathologic pattern of the individual tumor.

The prominent role played by the endothelial cells in all types of sarcoma is demonstrated by the formation of new blood vessels in the connective tissue stroma of the tumor; this is in contrast to the invasion of pre-existing blood vessels by carcinomas.

Histogenesis and histopathology The angiosarcomas have a tendency to form many functioning blood channels which are imperfect and immature as compared to the normal vascular substrate of adult organs or tissue. When these spaces become obliterated by proliferating edematous, atypical endothelial cells, growth ceases

and necrosis or various types of degeneration may be seen.

Many writers feel that the term 'angiosarcoma' should be reserved for those very vascular tumors in which formed blood vessels, rather than atypical, extremely hyperplastic endothelial-lined blood spaces, are observed.

The etiology of angiosarcoma, as with all forms of malignant lesions, is obscure.

Incidence and distribution. Data on 6 cases of angiosarcoma of the gastrointestinal tract were found in this review. Three lesions were thought to have originated in the stomach, while the others were considered as metastatic deposits from other parts of the body.

Freilich and Coe, in 1936 reviewed the reports of 50 cases in the literature over the period from 1918 to 1934, inclusive, and found only 1 case in which they felt that the lesion was primary in the gastrointestinal tract. The lesion in this case allegedly appeared in the jejunum.

Symptomatology, treatment, and prognosis. The most prominent symptom of this group of lesions was pain. This occurred first at the site of origin and later at the sites of metastatic lesions.

There have been a few cases cited in the literature in which exploration of the abdominal organs was carried out early enough to permit resection of a primary angiosarcoma before obvious metastasis had occurred.

Röntgen therapy has been of little or no value, and 3 of the 4 patients reported on in detail in the last named study survived only a few months after the onset of symptoms.

EXPERIMENTAL PRODUCTION OF MALIGNANT VASCULAR TUMORS

In recent years several different carcinogens have been identified and are used in the experimental production of malignant tumors. Selbie, in 1938, found that radioactive thorotrast injected subcutaneously acts as a foreign body and the resulting constant bombardment of alpha particles stimulates a continuous proliferation of connective tissue. If capillary endothelial cells are involved a hemangioendothelioma will develop. This was found to occur not only at the site of injection, but also in parts of the body distant from the point of initial irritation.

An interesting report was published by White and Stewart, in 1942 indicating that when certain strains of white mice were fed methylcholanthrene there developed precancerous epithelial lesions, adenocarcinomas of the intestine which metastasized to the mesenteric lymph nodes and liver and hemangioendotheliomas which involved

singly or in combination the intestine, mesentery and pancreas, and which, in turn, then metastasized to the liver and lungs. A higher incidence of hemangioendothelioma developed in one strain of mice than in others.

Andervont, Grady and Edwards, in 1942, injected 2-amino-5-azotoluene into the subcutaneous tissue of 63 mice. Subsequently 71 hemangioendotheliomas were found in these mice and most of the lesions were within fat deposits in the interscapular region, abdomen or subcutaneous tissues away from the site of injection. These authors stated that the etiology of this predilection for fatty tissue is obscure. Transplants were also successful, 1 tumor being carried for 30 generations. Other investigators have reported induction of hemangioendotheliomas at or near the site of administration of polycyclic hydrocarbons and colloidal thorium dioxide.

TREATMENT OF VASCULAR TUMORS

In contrast to the numerous and highly effective methods of treating vascular malformations and tumors of the skin and the mucous membrane of the mouth, tongue, and nasopharynx, the vascular lesions involving the lower part of the gastrointestinal tract are, by virtue of their position, difficult and often impossible to eradicate.

Surface applications of sclerosing agents are not practical for many deep-seated vascular tumors; however, refrigeration with carbon dioxide snow or the injection of sodium morrhuate has a limited application in the treatment of esophageal or rectal hemangiomas.

Plication of intraperitoneal vascular tumors with mattress sutures or ligation of their tributary vessels may be followed by progressive necrosis and rupture of the associated hollow viscus. The insertion of hot platinum needles or cautery fulguration has been utilized in a few cases in which danger from future necrosis of vital structures was not an important consideration.

Radium and roentgen therapy have proved valuable in the treatment of many vascular lesions both on the body surface and in the gastrointestinal tract. The effective roentgen and radium emanations produce swelling and degeneration of the endothelial cells.

Pack and Livingston have correlated the histopathologic features of vascular lesions with the amenability of the lesions to roentgen therapy. They stated that the capillary angiomatous of the skin seem radiosensitive; that the bulky cavernous hemangiomas in children tend to be radiosensitive, although there are better forms of treatment, and that the bulky cavernous hemangiomas of

adults are radioresistant except to caustic sclerosing doses.

Bailey and Kiskadden, on the other hand, found that the well differentiated endothelial cells of capillary hemangiomas are resistant to roentgen therapy.

It has been pointed out by MacKee that beta rays are more efficacious than gamma rays for superficial lesions however gamma radiations have given better results than filtered roentgen rays for deeper lesions.

Baensch, in 1938, treated cavernous hemangiomas of the body surface by the implantation of radium needles filtered through platinum and iridium. Excellent results were observed in 203 cases, with no bleeding or necrosis of the hemangiomas.

The mere fact that good results are reported by numerous authors using many methods and types of radiation therapy serves to prove that no single approach is applicable and successful in all cases.

The vascular lesions present special problems in radiation and surgical therapy which depend on the type of tumor and specific location in the gastrointestinal tract. These problems will be considered in the following section of this review.

ANALYSIS OF CASES

Vascular malformations and tumors of the gastrointestinal tract. Because of the confusion of nomenclature in the literature it is difficult to state the exact incidence of any individual types of either benign or malignant tumors of the gastrointestinal tract.

Geischickter in 1935 reviewed the reports of a large series of tumors appearing in these organs and found reference to 962 malignant tumors during the same period that he collected reports of 178 benign tumors. Six of the 178 benign tumors were angiomias, which accounted for approximately 3 per cent of the benign lesions.

Ackerman in 1937 found only 3 cases of hemangiomas of the gastrointestinal tract during a 10 year period in which 1 200 autopsies were performed.

Geischickter and Keesbey reviewed the data on 570 tumors of the blood vessels found in the surgical and autopsy records of the Johns Hopkins Hospital. They found in this group only 10 vascular lesions which involved either the kidney, spleen, intestines or mesentery.

Kujser in 1936 collected from the literature, reports of 74 vascular tumors found in the gastrointestinal tract, and classified the tumors.

Data on 344 benign and malignant vascular tumors involving the gastrointestinal tract were

collected in our review. Two hundred and eighty three of these lesions were classified as benign while the other 61 were considered malignant thus, approximately 82 per cent of the lesions were benign. One hundred and ten of the 344 cases were encountered in the surgical or autopsy records of the Mayo Clinic these 110 cases occurred among more than 1,400 000 persons. It can thus be estimated that roughly 1 in every 14,000 persons registered at the Mayo Clinic was found to have a benign or malignant vascular tumor involving the gastrointestinal tract.

Symptoms. In 66 per cent of all the cases of benign vascular tumor symptoms were mentioned whereas in all of the cases of malignant tumors symptoms were recorded.

Treatment. Thirty per cent of the patients with benign vascular tumors underwent surgical treatment, while 31 per cent of the patients with a malignant tumor of the gastrointestinal tract underwent some type of surgical exploration and treatment. Sixteen per cent of the malignant vascular tumors and 5 per cent of the benign vascular tumors were treated by other methods than operation.

Complications. Twelve per cent of the patients with benign vascular lesions and 48 per cent of those with malignant vascular lesions were mentioned as having died from some complication of the gastrointestinal tumor. Thirty four per cent of the benign vascular tumors, as opposed to none of the malignant vascular tumors, were mentioned as incidental findings during autopsy.

Sex ratio. Watson and McCarthy in their extensive series reported in 1940, cited a definite trend to indicate that benign blood and lymph vessel tumors occur more frequently in females. In their series, 65 per cent of the lesions occurred in females, and this frequency of occurrence was mentioned as a constant feature in the literature. The sex ratio was calculated however on the basis of all lesions, including those which appeared on the surface of the body as well as those in the viscera.

Our review of the lesions appearing in the gastrointestinal tract, on the other hand revealed a sex ratio of 1 female to 2 males among cases reported in the literature and a slightly higher ratio of approximately 1 female to 3 males in the Mayo Clinic series.

Vascular malformations and vascular tumors of the esophagus. Benign tumors of the esophagus are comparatively rare and the majority are amenable to some form of treatment. Malignant tumors, by contrast, are relatively common and very difficult to treat. The vascular lesions of the

Fig. 2. Cavernous hemangioma of the esophagus, multiple phlebectasia type. Note large vascular spaces lined by a single layer of endothelial cells (hematoxylin and eosin $\times 14$).

esophagus constitute a small minority of the aforementioned groups. Esophageal varices are not considered as primary vascular malformations and have not been included in this review.

Incidence. Sommer in 1896, and Bennecke in 1906, reported the first cases of multiple cavernous hemangiomas of the esophagus.

Vinson and his co-authors reported, in 1926, on the findings and treatment in a case of capillary hemangioma which was treated through the esophagoscope with a radium tube.

A summary of the data on the reported cases of vascular tumors of the esophagus, presented in Table II is based on the following lesions: 9 benign hemangiomas, 2 hemangioendotheliomas and 1 Kaposi's sarcoma.

One malignant and 9 benign vascular lesions were found also in the Mayo Clinic series and include the following: 1 mixed capillary and cavernous hemangioma, 6 multiple cavernous hemangiomas (Fig. 1), 1 simple polypoid cavernous hemangioma, and 1 hemangioendothelioma.

Symptoms. The symptoms from vascular tumors of the esophagus include slowly progressive dysphagia, regurgitation of food, pain in the thorax extending to the back and accentuated on swallowing, slow starvation, dyspnea if the tumor enlarges to obstruct the trachea, severe pain and subcutaneous emphysema following perforation, and, rarely, severe hematemeses and melena.

Among the benign vascular lesions found in this study 1 tumor perforated the esophagus with ro-

sulting mediastinitis and death, 7 tumors were incidental findings at autopsy and 1 tumor was associated with a carcinoma of the esophagus, which was perforated and caused death, and the hemangioendothelioma produced severe dysphagia, with complete esophageal obstruction and death.

Differential diagnosis. The lesions to be considered in the differential diagnosis of vascular neoplasms are the various types of malignant and benign tumors, esophageal varices, cardiospasm, and other demonstrable causes for dysphagia. Telangiectatic lesions are difficult or impossible of recognition, even when a bleeding point is observed, under direct vision with the esophagoscope.

Criteria for the roentgenologic diagnosis of benign and malignant esophageal tumors have been carefully defined; however accurate histopathologic diagnosis can, in the final analysis, be made only by esophagoscopy and biopsy.

Treatment. The three methods of treatment for vascular lesions of the esophagus include trans-thoracic surgical extirpation, roentgen therapy through numerous portals, and those procedures adapted for use with the esophagoscope. The method of choice depends on the particular location and type of the lesion.

Surgical extirpation may be carried out through a posterolateral, an upper posteromedial, or a transthoracic approach, depending on the location of the tumor. Polypoid tumors with a small pedicle may be excised, the esophageal continuity being maintained. Lesions occurring in the lower third of the esophagus may be resected in the manner now utilized for carcinomas involving the esophagogastric junction. Extensive malignant lesions involving the upper third of the esophagus might be considered for esophageal resection followed by the establishment of a cervicoesophageal fistula, the performance of a Beck-Jannu gastrostomy and, later, reapproximation of the esophagus and stomach through thoracic skin tube grafts. Local invasion and early metastasis along with all attendant hazards of multiple operations and the expense involved in long periods of hospitalization obviate the use of the last-mentioned operative procedure.

Roentgen therapy should be utilized only if treatment through the esophagoscope or thoracic surgical treatment is impractical. In no reported cases were the patients treated by this method alone.

Malignant change is rarely encountered in pedunculated lesions and several of these tumors have been removed through the esophagoscope. Radium packing, adjacent to a hemangioma, has

been reported by Vinson and his co-authors and may be considered in the treatment of very extensive benign vascular lesions; however, its attendant hazards, esophageal perforation or severe hemorrhage, must be remembered.

Moersch, in 1940, reported the injection of esophageal varices with sodium morrhuate. This procedure may be applicable to hemangiomas when encountered in the future.

The series of esophageal vascular malformations and tumors reported in this study is too small for any generalizations as to prognosis, however all 3 patients with symptoms produced by hemangio tumor were dead within 1 year.

Vascular malformations and vascular tumors of the stomach. Vascular malformations and vascular tumors are rarely encountered in the stomach; however their importance is emphasized by a high incidence of severe complications, the frequent occurrence of malignant change, and the satisfactory prognosis after adequate removal.

Incidence of benign vascular tumors. Rokitsansky (209) in 1855 alluded to the first gastric hemangioma by stating that 'erectile tumors' may be attached by a broad base; however Lammers, in 1893, gave the first detailed description of a capillary hemangioma found at autopsy.

In 1920 Lemon collected the reports of the first 5 gastric hemangiomas to appear in the literature and added 1 case of his own.

Since this first series of collected cases, numerous reports have appeared in the literature. These are summarized in Table II.

The reported incidence of hemangiomas as compared to other benign gastric tumors has been listed as between 1.6 and 14.7 per cent. This discrepancy depends largely on whether material has been collected from surgical or autopsy records.

The reports of the vascular malformations and benign vascular tumors of the stomach collected from the literature for our review include the following: 11 cases of multiple telangiectasia, 3 of capillary hemangioma, 1 case of mixed capillary and cavernous hemangioma, 4 cases of multiple phlebectasia, 1 case of diffuse expansive cavernous hemangioma, 2 cases of multiple diffuse expansive cavernous hemangioma, and 5 of unclassified hemangiomas. This makes a total of 27 benign vascular lesions.

Four benign vascular tumors of the stomach were found in the Mayo Clinic series. They were classified as follows: 1 capillary hemangioma (Fig 2), 1 mixed capillary and cavernous hemangioma, and 2 polypoid cavernous hemangiomas.

Incidence of malignant vascular tumors. Malignant lesions derived from the connective tissue

Fig 2. Capillary hemangioma of the stomach, 11 by 3 by 2.5 cm. Note ulceration of the mucosa at the distal end (top) of the tumor.

and supporting structures such as the blood vessels are rarely encountered in the stomach.

Dahlgren in 1934, reviewed the reports of 11 previously described endotheliomas in the literature and added 1 case of his own. He mentioned the following histopathologic classification of these lesions: endothelioma with no further descriptive terms, 6 cases; lymphangioendothelioma, 3 cases; hemangioendothelioma, 1 case; perithelioma or capillary hemangioendothelioma, 1 case. In 1 case no microscopic details were given.

Lemon and Broders, in 1942, stated that sarcomas have been estimated variously to comprise from 1 to 8 per cent of all neoplasms of the stomach. They published a review of 14 cases which included leiomyosarcomas, fibrosarcomas and 2 hemangioendotheliomas. They postulated that this low ratio of 2 hemangioendotheliomas seemed reasonable because of the abundance of smooth muscle in the stomach as compared with the amount of vascular endothelial tissue.

Data on the malignant vascular lesions of the stomach which were reported in the literature are summarized in Table II. These lesions included 3 hemangioendotheliomas, 12 endotheliomas, and 8 Kaposi sarcomas. Records of 7 cases of hemangioendothelioma (Fig 3) of the stomach were

found in the Mayo Clinic series. The clinical details are given in Table 3.

Symptoms. There are no characteristic digestive symptoms which may be attributed to benign tumors in the stomach. Minnes and Geschickter stated that in their series of 50 cases, 36 patients gave no indication of the presence of a lesion.

In our collected review of 33 cases of benign vascular tumors of the stomach we found that symptoms developed in 24 cases as follows: vague gastric distress in 2 cases, pain in 2, weight loss in 2, hematemesis in 4, melena in 12, fatigue in 3, vomiting in 1 case and death followed severe gastric hemorrhage in 4 cases.

Bleeding from these hemangiomas may be of two types: the patient may have a severe hemorrhage with hematemesis and melena, or the blood may be lost by minimal persistent oozing, with associated signs of secondary anemia.

The hemangiomas often project into the gastric lumen and tend to develop a pedicle as a result of peristaltic activity. This occurred in 3 of the 4 cases reported in the Mayo Clinic series. Pyloric obstruction from a ball valve action of the tumor may cause pain, nausea, and severe vomiting.

Symptoms of malignant vascular tumors. The symptoms produced by the malignant vascular lesions included pain in 8 cases, hematemesis in 5, weight loss and marked weakness in 3, melena in 7 and vomiting in 1 case. A palpable mid epigastric mass was noted in 2 cases.

Patients with malignant vascular lesions of the stomach often give a history of vague epigastric distress for many years followed by a long period without complaints. A return of progressive severe symptoms brings them to a physician for diagnosis. This historical sequence occurred in 4 of the 7 patients in the Mayo Clinic series.

Differential diagnosis. The development of the flexible gastroscope and the establishment of more accurate roentgenologic criteria have made the differential diagnosis between benign and malignant lesions more accurate; however all tumors appearing in the stomach must still be considered malignant till proved benign by examination under the microscope. This requires biopsy or complete surgical extirpation.

The gastroscopic appearance of multiple telangiectatic lesions was first described by Renshaw in 1939. Pigmented spots and chronic localized gastric purpuric lesions must be considered in the differential diagnosis.

Treatment. The treatment of all vascular malformations and vascular tumors, when possible, should be complete surgical extirpation. When one is confronted with a specific gross vascular

lesion of the stomach, the chances are against that lesion's being or remaining benign and, even though some method for adequate biopsy might be developed, the risk of the complications of ulceration, bleeding, and later malignant change would still outweigh the risk of surgical treatment in all but the most extensive lesions.

The type of resection indicated depends on the position and extensiveness of the lesion and on the operative risk for the individual patient.

Judd and Hoerner in 1936, summarized their indications for removal of benign tumors as follows: (1) small, single, symptomless lesions high on the cardia are inaccessible and local excision may be advantageous; (2) gastrojejunostomy must be considered in all cases of local excision to overcome any tendency toward gastric retention secondary to interference with gastric motility; (3) a Billroth I type of resection may be utilized in lesions near the pylorus; (4) Billroth II and Polya operations are best considered for treatment of large tumors; and (5) multiple lesions require radical resection.

The polypoid tumors of the stomach are all potentially malignant, and with the decrease in mortality following wide and extensive gastric resections during the past decade, together with minimal postoperative gastric symptoms, the risk of possible malignant changes in the pedicle and surrounding tissue far outweigh the risk of radical resection except in the few cases in which a potentially high morbidity or mortality rate prevails with any type of abdominal exploration.

Abdominal exploration and gastric resection is the treatment of choice for all malignant vascular lesions regardless of the histopathologic structure. Many lesions are found to have a sharp line of demarcation from other viscera and, in spite of size, many have been resected with excellent results. A summary of the clinical findings, methods of treatment, and the results is given in Tables I, II, and III.

Local application of radium is impossible in the stomach and radon needles would be a very poor substitute for radical surgical treatment. Roentgen rays may be used in the treatment of very extensive cavernous hemangiomas which involve many intra-abdominal structures and cannot be resected. Several cases of this type are mentioned in the literature but follow-up studies are inadequate.

Prognosis. Osler (183) Boston, Watson and McCarthy and Stellar have all cited cases of gastric telangiectasia in which death resulted from hemorrhage; however many patients with this type of lesion continue with intermittent

Fig. 3. Hemangioendothelioma, grade 1 of the stomach, with imperfect formation of sinuses or capillaries. There is moderate variation in the size and shape of fusiform endothelial cells, with elongated nuclei and rare mitotic figures (hematoxylin and eosin $\times 173$)

Fig. 4. Hemangioendothelioma, grade 1 of the duodenum. Note moderate anaplasia of fusiform and oval-shaped endothelial cells, arranged in masses around imperfect capillaries or forming papillary projections in larger cavernous spaces (hematoxylin and eosin $\times 173$)

gastric hemorrhages throughout life and die of other unrelated conditions.

Many factors influence the prognosis for patients with vascular lesions in the stomach. These include the general surgical risk with regard to the particular patient, the type, extensiveness and metastatic spread of the lesion, and the surgical complications associated with and following removal of vascular tumors. A summary of the data in these cases is presented in Tables II and III.

A large majority of the patients with benign lesions had no further symptoms after surgical extirpation of the vascular tumor. Of 7 patients with hemangioendotheliomas of the stomach observed in the Mayo Clinic series, 3 were living and well 20 years after surgical treatment, 2 were living 7 and 4 years respectively, after surgical treatment, 1 patient, with a high grade hemangioendothelioma, died of extensive recurrence from the original lesion 8 years after operation and roentgen therapy and 1 could not be traced.

Vascular malformations and vascular tumors of the duodenum. Although benign tumors of the duodenum are extremely rare, their incidence is only slightly lower than that for primary malignant growths occurring in the same segment of the gastrointestinal tract.

Laboulbène, in 1872 reported the death of a patient following severe hemorrhage from an almond-sized duodenal tumor which contained both capillary and cavernous blood-filled spaces. Since

the time of this early case report only 6 other benign vascular tumors have been mentioned in the literature. Five of these were cavernous hemangiomas, while no histopathologic details were presented of the sixth one.

Two simple polypoid cavernous hemangiomas and 8 hemangiomas of the multiple phlebectasia type were found in the duodenum in the Mayo Clinic series. Several polypoid cavernous hemangiomas which prolapsed into the duodenum from the gastric side of the pylorus are not included.

Kaposi's sarcoma involved the duodenum in 4 cases reported in the literature while a record of 1 hemangioendothelioma, grade 1 (Fig. 4) was found in the Mayo Clinic series.

Symptoms, treatment, and prognosis. Tumors of the duodenum cause no characteristic symptoms. The important clinical features which bring them to the attention of the physician are obstruction and bleeding. Many lesions are first encountered at the time of roentgenologic examination which is made because of vague gastrointestinal distress.

When a tumor is palpated in the duodenum during a surgical procedure it is important to determine its site of origin in order to avoid an unnecessary duodenostomy or duodenectomy for a prolapsing gastric lesion. Manipulation of the tumor may push it back through the pylorus into the stomach where a gastrotomy or gastrectomy is then possible.

Fig. 5. Cavernous hemangioma of the jejunum, multiple phlebotasia type. Note large blood-filled endothelium-lined spaces with connective tissue septa (hematoxylin and eosin $\times 24$).

Polypoid vascular lesions of the duodenum may be removed by local excision and transverse closure of the operative defect; however with moderately extensive tumors and a mobile duodenum, partial duodenectomy and even associated partial gastrectomy may be indicated.

Ackerman, in 1937, performed an autopsy in a case in which there were 2 nodular hemangiomas of the duodenum. These tumors had ruptured into the retroperitoneal space where 400 c.c. of blood had collected.

Reports on 16 benign vascular tumors were found in our review of the literature. Seven of these were ulcerated and produced severe gastrointestinal hemorrhages. One compressed the common bile duct and caused progressive jaundice and hepatic failure. Two produced symptoms of partial duodenal obstruction. Nine lesions produced no known symptoms during life. Three patients were free of symptoms after surgical extirpation of the lesion. Five patients died as the direct result of some complication from the benign vascular tumor.

Data on 5 malignant vascular tumors of the duodenum were collected from the literature and from the records of the Mayo Clinic. Four patients died of complications from a Kaposi sarcoma. One patient was living 4 years after surgical extirpation of a hemangioendothelioma, grade 1.

Vascular malformations and vascular tumors of the small intestine. The occurrence of vascular

malformations is closely correlated with the embryologic development of the circulatory system in the small and large intestines. The main branches of the mesenteric arteries which supply the intestines are formed early in the mammalian embryo. The earliest capillaries then develop in a fairly definite plane which corresponds to the future submucosa. From this capillary layer the earliest vessels allegedly sprout and form the rami which nourish the smooth muscle and mucosa of the small intestine. Congenital developmental anomalies of the vascular system are more likely to arise in this active, early developmental layer. The formation of a large part of the small intestine occurs in the later months of fetal life and it is thus reasonable to assume that there is a greater chance that fetal rests remain in this segment of the digestive system. This postulate is substantiated by the observation that more vascular tumors occur in the small intestine than in any other segment of the gastrointestinal tract.

Incidence. Gascoven is given credit for reporting in 1860, the first case of hemangioma of the small intestine. Since that time numerous case reports and reviews have mentioned the general incidence of vascular lesions in the small bowel.

Dewis, in 1906, and Helvestine, in 1913, cited the incidence of hemangiomas in the small intestine to be around 1 per cent by comparison with other benign tumors, whereas Geschickter in 1935 and Merchant, in 1939, considered a much higher figure, 10 or 12 per cent, to be more representative.

Reports on 67 benign vascular lesions of the small intestine were found in the literature and 51 similar tumors were examined in our study of the Mayo Clinic series. The total group of 118 tumors of the small intestine represented more than 41 per cent of all benign vascular lesions found in the gastrointestinal tract during this review. A detailed summary of these cases, including the histopathologic features of the tumors, is presented in Tables II and III. A section of a cavernous hemangioma of the jejunum is shown in Figure 5.

The incidence of malignant vascular tumors, when compared with that of malignant lesions found in the small intestine, was given by Mayo as about 1 per cent. In our review 18 malignant vascular tumors were found to involve the small intestine. This group included 6 hemangioendotheliomas, 10 Kaposi sarcomas, and 2 "benign metastasizing hemangiomas."

It may be seen that, contrary to the fact that usually more malignant than benign lesions of a similar histopathologic type involve the small in-

Fig 6 Transillumination of the ileum reveals translucent valvulae conniventes, submucosal vascular plexus and multiple, opaque, cavernous hemangiomas, multiple phlebectasia type.

testine in our study only 18 malignant as opposed to 118 benign vascular tumors were found thus, 87 per cent of the vascular lesions were benign.

Symptoms. Mucosal ulceration and bleeding is a frequent complication of all tumors located in the small intestine. There is, however a greater risk of exsanguinating hemorrhages associated with vascular lesions because, like old duodenal ulcers which have inflammatory scar tissue and sclerosed blood vessels at their base the parenchyma of vascular tumors does not have functioning smooth muscle to act as a protective mechanism to close off the large vascular bed from the intestinal lumen. Nineteen per cent of the benign vascular tumors and 30 per cent of the malignant vascular tumors tabulated in this review presented clinical evidence of gastrointestinal bleeding. Four patients died of severe hemorrhage and 4 others died of some complication following operation.

Vascular lesions of the small intestine may produce either partial or complete obstruction by gradual encroachment on the lumen of the bowel or by prolapse and intussusception. The slowly enlarging vascular lesions are associated with vague recurring abdominal pains, distention gurgling and increasing constipation. Nausea and vomiting appear late in the course of the disease.

Benign tumors of the small intestine are often cited as the greatest single etiologic agent responsible for intussusception in adults. Nicoll in 1899 described a double intussusception at the site of a cavernous hemangioma of the small bowel.

Fig 7 Diffuse cavernous hemangioma of the jejunum, ileum, and mesentery.

A review of the data on vascular tumors in the small intestine indicated that pain, nausea, vomiting and perhaps abdominal resistance were the most prominent features in 13 cases, whereas only 4 lesions had actually caused intussusception at the time of operation.

Differential diagnosis. Naumann has described chylangiomas of the intestine which have the same histologic structure as hemangiomas. Their endothelial spaces contain a gelatinous pink staining material derived from lymph.

A second differential point, to be considered at the time of operation, is chronic congestion of the portal system which may produce saccular dilatations of subserosal and even submucosal veins. The histologic pattern of these lesions is similar to that of veins and not to that of cavernous hemangiomas. Transmitted light may demonstrate a sacculatation of the vein wall, which is in contrast to what occurs in hemangiomas which have a separate blood supply and a convex surface toward large veins in the vicinity (Figs. 6 and 7).

Treatment and prognosis. Complications such as intestinal obstruction, intussusception, and severe hemorrhage may require immediate operative intervention after the circulating blood vol

Fig 8. Diffuse cavernous hemangioma of the vermiform appendix. The serosa of the cecum was also covered by this vascular lesion (hematoxylin and eosin $\times 24$).

ume and the chemical balance have been restored to as near normal as practical and after anemia has been corrected. Extraluminal benign vascular tumors may be extirpated without incising the mucous membrane or endangering the blood supply of the associated bowel. Resection of a segment is necessary in some cases because of size, extension, and possible malignancy of the lesion.

Palliative forms of treatment such as cauterization, partial extirpation, roentgen therapy, implantation of radon seeds, and injection of sclerosing solutions should be considered only for lesions that are too extensive for adequate resection.

Of 67 benign vascular lesions of the small intestine cited in the literature, 15 were excised with recovery of the patient, and 5 patients died after operation. Fifty-one similar intestinal lesions in the Mayo Clinic series were evaluated in our study 3 of which were excised with the patients living 5 years after operation, 2 were found too extensive for resection and 46 caused no known symptoms during life.

One hemangioendothelioma in the small intestine was excised and affected nodes were found at operation. The patient died 14 months after the onset of symptoms, of extensive local recurrence and metastasis from the original tumor which was graded 3. Another patient with a hemangioendothelioma, grade 1 was living and well 3 years after operation.

Vascular malformations and vascular tumors of the appendix. Dandy in 1914, after a thorough

search of the literature, was able to collect 10 examples of benign tumors of the appendix and presented the first review of this condition. No vascular tumors were found in this group.

Miescher in 1923, described an angiofibroma which occurred in the appendix. The symptoms, not unlike those of acute appendicitis, resulted from torsion of the appendix and the associated lesion. The appendix was 17 cm. long and all portions of the vascular system were reproduced in the contiguous tumor.

Since the time of the first report, 2 other vascular tumors of the appendix have been cited in the literature and 4 cases were found in the Mayo Clinic series (Figs. 8, 9 and 10). A clinical summary of these is presented in Tables II and III.

One of the 3 patients cited in the literature and 1 of the 4 patients mentioned in the Mayo Clinic series had symptoms consistent with those of acute appendicitis. Three vascular lesions were noted during surgical exploration for other conditions, while 2 cases were not reported in detail. The appendix was removed in 5 of the 7 cases. No postoperative complications or subsequent death could be attributed to the presence of these vascular tumors. One patient in the Mayo Clinic series had a hemangioendothelioma, grade 1. He died at home, 2 years after resection of the tumor during a tonsillectomy.

Vascular malformations and vascular tumors of the colon, rectum and anus Increasing emphasis has been placed on improvement of diagnostic methods as applied to the study of intestinal dysfunction. The appearance of gastrointestinal bleeding, cramping abdominal pains, or any change in bowel habits is now evaluated not only by the study of stool specimens but by extensive use of the proctoscope, sigmoidoscope, and roentgenoscope. Consequently many of the rare lesions such as the vascular tumors are now more frequently encountered, and further emphasis on reporting these cases in the literature has led to a better understanding of their relative incidence, complications, treatment, and prognosis.

A comparison of numerous reports and various estimates of the general incidence of vascular tumors of the colon shows a marked discrepancy depending on whether surgical material or autopsy specimens are examined. The incidence observed at autopsy also depends on the care taken to note benign lesions, whereas the incidence at operation is higher for those lesions which commonly produce severe symptoms.

Bensaude and his coworkers (26) in 1932 classified 15 cavernous hemangiomas of the rectum, sigmoid, and anus which had been reported in the literature. They arbitrarily separated them into the ano-recto-sigmoidal cases in which involvement of the skin did not occur and the genito-perineo-rectal types in which involvement of the skin did occur. Eleven lesions were confined to the mucous membrane and 4 caused related involvement of the skin.

Hunt in 1941 stated that there were apparently only 20 cases recorded in the literature in which hemangioma had been encountered in the large bowel at operation or autopsy.

Reports of 61 benign and 9 malignant vascular lesions located in the colon and rectum were found in the literature and summarized in our review. That is, of 234 benign and malignant vascular lesions which were found in the gastrointestinal tract, 70 lesions or 30 per cent, were located in the colon, rectum, and anus.

Thirteen benign and 2 malignant vascular tumors were found in the Mayo Clinic series. Thus, from a total of 110 vascular lesions spread throughout the gastrointestinal tract, 15 lesions, or 14 per cent, were located in the large bowel, rectum, and anus.

Data on the cases of vascular lesions occurring in the colon, rectum, and anus are given in Tables II and III.

Symptoms. In patients with vascular lesions of the colon symptoms may develop from either

Fig. 10. Hemangioendothelioma, grade 1, of the vermiform appendix. Note vascular spaces or cavities surrounded by polygonal endothelial cells with oval or fusiform nuclei and with scattered mitotic figures (hematoxylin and eosin $\times 85$).

intestinal obstruction or severe hemorrhage. Cavernous hemangioma must be considered in the differential diagnosis of any rectal bleeding during the first year of life.

The patients in 42 of the 85 cases encountered in our review had either acute or chronic episodes of bleeding into the bowel lumen; therefore since 16 vascular lesions were noted only as incidental findings at autopsy in 42 of 69, or 61 per cent, of the clinical cases some type of intestinal hemorrhage was demonstrable. The serious prognosis for patients with a diffuse expansive cavernous hemangioma of the colon or rectum has been considered in the section on pathology.

Vascular lesions may produce acute or chronic intestinal obstruction as a result of (1) gradual enlargement of the lesion with resulting occlusion of the intestinal lumen, (2) intussusception or (3) volvulus. Obstructive symptoms were observed in 12 of the 69 clinical cases found in this review.

Vascular lesions occurring in and around the rectum may cause urgency, rectal tenesmus, incomplete stool evacuation, and the sensation of prolapse or extrusion of a mass from the anus. A primary cavernous hemangioma in this location may erode through the bowel wall into contiguous structures. Rectovaginal fistulas developed in 2 cases.

Differential diagnosis. The criteria for roentgenologic diagnosis of vascular lesions in the colon

Fig. 11. Single polypoid cavernous hemangioma of the rectosigmoid. N is large submucosal blood filled spaces with thrombosis and calcium deposits (hematoxylin and eosin $\times 24$).

are similar to those for other tumefactions occurring in this segment of the intestinal tract. Phleboliths or calcareous concretions may form in the cavernous spaces of a hemangioma and have been observed in a few cases during roentgenologic examination. Digital examination reveals the nodular character of rectal lesions and, on direct proctoscopic observation, they appear bluish in color from the blood which may be aspirated from the vascular sinuses.

Treatment. The treatment of these lesions depends, as in other types of benign and malignant tumors, on their location, degree of extension, and their association with other intraperitoneal structures.

The capillary hemangioma, mixed capillary and cavernous hemangioma, and the simple polypoid cavernous hemangioma may be removed by transcolonic excision; however the benignancy of large lesions may be questionable and, in this event, radical resection of the contiguous segment of colon and associated mesenteric nodes carries a better prognosis.

Multiple cavernous hemangiomas of the phlesectasia type seldom produce symptoms and, unless a definite source of bleeding is noted at the time of operation, any type of resection is associated with a higher mortality rate than is conservative management.

The single and multiple diffuse cavernous hemangiomas (Figs. 11, 12 and 13) present the most serious complications of all benign vascular

Fig. 12.

Fig. 13.

Fig. 12. Extensive diffuse cavernous hemangioma of the sigmoid and rectum. A second cavernous hemangioma was found in the pelvis of the right kidney.

Fig. 13. Multiple, diffuse, cavernous hemangiomas of the arm, scrotum, and penis. A single, ulcerated, polypoid, cavernous hemangioma was removed from the sigmoid.

tumors and are extremely difficult to treat. Many of these lesions are very extensive and involve other intra-abdominal structures, a fact which, with radical resection, leads to a prohibitive surgical mortality rate. Ligation and injection of the vascular bed supplying a large cavernous hemangioma has a very limited field of application, not only because of the danger from intestinal necrosis or severe hemorrhage, but also because few hemangiomas, unless very small, have disappeared after a single injection of sclerosing solution. Operations which sidetrack the lesion have been undertaken but these procedures alone leave a potential source of hemorrhage. Colostomy followed by high voltage roentgen therapy, has been successful in a few cases. Resection of the scarred and stenosed colon together with the remaining partially sclerosed tumor may then be considered.

Many of the diffuse cavernous hemangiomas of the rectum and sigmoid colon are so extensive that combined abdominoperineal resection or posterior

Fig. 14. Hemangioendothelioma of the rectum, grade 1 with spindle-shaped and oval-shaped endothelial cells in-losing imperfect capillaries. Rare giant cells and mitotic figures are visible (hematoxylin and eosin $\times 173$)

resection seems impractical however, the prognosis for the patient has been so serious that extensive resection should be carefully considered.

The hemangioendotheliomas (Figs. 14 and 15) should be widely excised and high voltage roentgen therapy or local application of radium should be used in the postoperative period.

SUMMARY

This study included a review of the available literature on the subject of vascular malformations and vascular tumors which involve the gastrointestinal tract. Because of the extreme infrequency with which these cases occur it seemed desirable that every report encountered in the literature be summarized to amplify our knowledge of this subject. Data on 189 cases of benign vascular lesions and 45 cases of malignant vascular lesions were collected from the literature.

The clinical histories and pathologic specimens on 94 cases of benign vascular lesions and 16 cases of malignant vascular lesions of the gastrointestinal tract, found at operation or autopsy at the Mayo Clinic, were also available for study.

The histogenesis of vascular lesions is frequently obscure, therefore, a more practical method of classification has been presented, which is derived from a study of the histopathologic structure of the lesions.

A review of studies on the experimental production of metastasis, and transplantation of hemangioendothelioma in white mice has been presented.

The symptoms, diagnosis, and treatment of vascular lesions depend on the specific anatomic segment of the gastrointestinal tract which is involved as well as on the histopathologic structure of the lesion; therefore, a study of each separate unit of the digestive tract has been included in this review.

CONCLUSIONS

1 Vascular malformations and vascular tumors are among the rarest lesions found in the gastrointestinal tract. It has been roughly estimated from this study that they occur once in approximately 14,000 patients.

2 The histogenesis of vascular tumors of the gastrointestinal tract is obscure however a consideration of their histopathology can be of assistance in determining adequate methods of treatment and prognosis.

3 Hemangiomas are rarely of one pure type. Classification of them depends primarily on grouping together different lesions which have the same cellular arrangement.

4 The criteria for an absolute diagnosis of gastrointestinal telangiectasia, as with other vascular lesions, should be limited to those based on histopathologic study.

5 Although in some of the reported cases of gastrointestinal telangiectasia death followed a severe hemorrhage (14 per cent) radical extirpation of these lesions is impractical because of their multiplicity and their tendency toward spon-

taneous regression. Repeated injections of moccasin venom or the administration of rutin may decrease the tendency to bleed.

6. A large majority of the patients with a capillary hemangioma of the gastrointestinal tract experienced symptoms during life (89 per cent) surgical extirpation was undertaken in many (78 per cent) and only a few died as a direct result of their lesion (11 per cent).

7. The mixed capillary and cavernous type of hemangioma may be a transition stage between the two major developmental groups or it may result from evolutionary changes which appear in every hemangioma with growth and aging.

8. The cavernous hemangioma of the multiple phlebectasia type is more commonly observed, both at operation and autopsy than is any other vascular lesion found in the gastrointestinal tract.

9. The polypoid vascular tumors tend to cause intussusception and obstruction, whereas the sessile lesions are more likely to develop surface ulceration and produce gastrointestinal hemorrhage.

10. The majority of small benign vascular lesions of the gastrointestinal tract are associated with the submucosal capillary plexus, whereas the diffuse expansive cavernous hemangioma involves large arteries and veins.

11. The diffuse cavernous hemangioma tends to expand over the surface of adjacent structures in the peritoneal cavity not associated with the gastrointestinal tract; however, unless the normal vascular segment which supplies these other organs or tissues demonstrates cavernous changes there will be no communication between the tumor and the blood supply of the contiguous normal structure.

12. When multiple and often mobile deposits of calcium are seen on roentgenographic examination, the diagnosis of a vascular tumor should be considered.

13. More than two-thirds of the benign vascular tumors of the gastrointestinal tract were found in males, whereas the malignant vascular tumors were about equally divided between the sexes.

14. The evidence indicates that a majority of all benign vascular tumors (66 per cent) and all malignant vascular tumors of the gastrointestinal tract produce symptoms during the patient's life.

15. The hemangioendothelioma is more frequently observed than any other type of malignant vascular lesion found in the gastrointestinal tract.

16. Many of the hemangioendotheliomas appear in young adults who may give a history of relatively long duration of symptoms. The prognosis is excellent for those patients with low

grade lesions which are surgically excised and followed by extensive radiation therapy. The higher grade lesions metastasize early to both local and distant parts of the body through the lymphatic channels or blood stream, and the patients are rarely cured after removal of the primary growth, even when removal is followed by extensive radiation therapy.

17. Many benign and malignant vascular tumors of the gastrointestinal tract encountered in our review of the literature and in the Mayo Clinic series were surgically excised and the patients had no further symptoms (50 per cent).

18. Unless more patients who have gastrointestinal bleeding of indeterminate origin, symptoms and signs of intestinal obstruction, or a freely movable abdominal mass are given the benefit of abdominal exploration, 1 of 9 patients with a benign vascular tumor and 1 of 2 patients with a malignant vascular tumor will die according to the data obtained in our investigation.

19. The small intramural or sessile vascular tumors of the esophagus rarely produce symptoms; however, those which cause obstruction or hemorrhage have, thus far, been incompatible with life.

20. Vascular malformations and vascular tumors of the stomach are rarely encountered; however, their importance is emphasized by a high incidence of severe complications, the frequent occurrence of malignant change, and the satisfactory prognosis after their adequate surgical removal.

21. Contrary to the belief that usually more malignant tumors than benign tumors are found in the small intestine, we found that 82 per cent of the vascular tumors were benign.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Visual Protection in Aerial Warfare. P. C. LIVINGSTON. *Br J Ophth*, 1948, 31: 669.

The introduction of equipment aimed at preserving vision of aircrew personnel requires maintenance of morale, that they not become eye conscious, and that they use the equipment on operational duty. The low number of eye injuries sustained by the Royal Air Force in flying operations indicates the value of a planned campaign against ocular injuries.

The preservation of sight can be aided by the use of bullet proof glass screens and armor plates, whose use is restricted by weight. Further protection can be effected by the use of safety glass in flying goggles, which can also be ground to correct refractive errors. Contact lenses are of limited use because of intolerance due to ocular sensitivity. An indirect method of protection was visual training to quicken the powers of recognition of aircraft and improving rod vision under conditions of low illumination.

FRANK W. NEWELL, M.D.

Histological Findings in a Case of Angioid Streaks. F. H. VICKROY. *Br J Ophth*, 1948, 31: 331.

The author discusses angioid streaks of the retina. Ophthalmoscopically this basophilic condition (calcification) brightens the contiguous fundus and renders more conspicuous the dark red choriocapillaris exposed by the ruptures in Bruch's membrane (producing streaks). Proliferative changes which may occur along or within the streaks may alter their appearance.

Ruptures which occur in senile eyes do not widen into visible streaks probably because the senile choroid loses its elasticity before Bruch's membrane becomes calcified.

Other lesions of the macula in cases of angioid streaks are due to proliferative changes affecting the pigment epithelium (senile degenerative changes). The subretinal hemorrhages in the macula and elsewhere are ascribed to fractures of the calcified membrane causing ruptures of the choriocapillaris. If such a hemorrhage elevates the pigment epithelium in the macula, "disciform degeneration" results.

Hemorrhages within the retina, as well as circinate retinitis are attributed to the vascular changes that commonly occur in cases of angioid streaks.

It is difficult to explain the presence of angioid streaks in association with some cases of pseudoxanthoma elasticum, with Paget's disease, with cardiovascular disease, and in some cases as an isolated phenomenon. The associated conditions may be dependent upon heredity.

According to histologic examination angioid streaks represent ruptures of Bruch's membrane. The gaps are widened by the elastic tension of the choroid.

JOSUEA ZUCKERMAN, M.D.

Participation of the Ocular Appendages in Sympathetic Ophthalmia and Its Bearing on Enucleation. BERNARD SAMUELS. *Br J Ophth*, 1948, 31: 369.

The author divides his paper into several sections. The first section has to do with the nature of sympathetic ophthalmia. In it he declares that this condition is in the nature of an infiltration and selective affinity for uveal tissue, but a characteristic feature of the condition is the tendency of spread outward beyond the globe.

The next section has to do with the pathways of the virus, namely, (1) along the uveal tract, (2) through the globe into tissues of the orbits, and (3) into the optic nerve. Histologic sections show the infiltration process in the orbit outside of the globe and in and around the optic nerve. The nerve sheaths are involved only in far advanced cases.

In the last section the author concludes that when the exciting eye is enucleated as a preventive measure before signs of inflammation are seen in the second eye, an ordinary, simple enucleation is sufficient. However if signs of inflammation appear in the second eye the enucleation of the exciting eye should include removal of the inferior oblique muscle, the optic nerve as far as possible, the retrobulbar tissues almost to the apex of the muscle cone, and the globe itself. The wound should be left open to drain.

EARL H. MEER, M.D.

Radiotherapy of Malignant Intraocular Neoplasms. H. B. STALLARD. *Br J Ophth*, 1948, 31: 62.

Radiotherapy is excellent for retinal glioma, but the treatment of malignant melanomas by radon seed is not satisfactory. Metastatic carcinoma of the eye requires treatment of sufficient strength to destroy it and yet not destroy the eye. This is difficult and the object of this work.

The treatment is done with plaques of platinum or silver 0.5 mm. thick containing radium salt, curved to fit the sclera over the site of the neoplasm, and fixed by sutures through the episclera at this point. The advantage is a more even and accurate distribution of irradiation to the neoplasm. Illustrations are shown.

The dose given is the maximum dose that the eye tissues will stand without serious destructive changes. A dose of 3,500 roentgens seems quite effective.

The results are good when the neoplasm occupies one quadrant of the globe or less.

The complications commonly encountered are (1) cataract (2) retinal detachment, (3) intraocular hemorrhage, and (4) shrinkage of the globe.

EARL H. MERR, M.D.

Goniotomy for the Relief of Congenital Glaucoma.
OTTO BARKAN *Brit J Ophth* 1948, 32 701

Goniotomy is an operation for stripping or peeling embryonic tissue from the angle wall. The author has used the technique in 76 eyes with congenital glaucoma and in 66 of these the pressure was normalized and vision was maintained or restored.

The early symptoms of congenital glaucoma are due to an increase in intraocular pressure and consist of corneal cloudiness, hyperemia of the bulbar conjunctiva, photophobia, epiphora, and blepharospasm. The onset of symptoms is usually before the fourth month and in some cases may occur with extreme suddenness.

The ocular hypertension causes corneal cloudiness which in the early stages is completely reversible by surgery or with drugs. Persistence of the cloudiness causes a milky opacification and irregular astigmatism which prevents the development of central vision. Optic atrophy occurs only after the intraocular pressure has been elevated for a long period.

The angle in congenital glaucoma shows the iris to be inserted anterior to its normal position by means of adventitious mesodermal tissue. The area of transition from the anterior surface of the iris to the posterior surface of the cornea consists of gelatinous looking semitransparent substance. In eyes successfully operated upon the embryonic tissue was stripped from the angle through one fourth to one third of its circumference.

The operation is indicated in all cases of congenital glaucoma in which the increased pressure is the result of obstruction of the angle by persistent embryonic tissue. In general, the earlier the operation is done after the onset of symptoms the more effective it is in restoring vision. Goniotomy is contraindicated in eyes in the advanced stage with scarring and a corneal diameter of more than 15 mm.

The operation is performed under ether-oxygen anesthesia. The initial success is enhanced if a contact lens is used with marked cloudiness of the cornea. Preliminary abrasion of the corneal epithelium permits its use. An assistant maintains fixation and with the contact lens in position the anterior chamber is entered with a goniotomy knife 1 mm anterior to the limbus in the superior inferior temporal quadrant. The knife crosses the pupil, its blade is inserted anterior to the root of the iris, and then rotated counter clockwise in this plane as long as visibility permits. The knife is then removed and a few seconds later a slight venous oozing occurs which is absorbed in a few hours. Eserine ointment and binocular pads are applied.

Complications include failure to strip the angle, indolent ulcers and hemorrhage. Early diagnosis and prompt surgery are essential for good results.

FRANK W. NEWELL, M.D.

EAR

Reconstruction of the External Ear. HERBERT CONWAY, CHARLES G. NEUMANN, JEROME GELB, LEO L. LEVERIDGE, and JULIUS M. JOSEPH. *Ann. Surg.* 1948 128 216.

Reconstruction of the external ear for the correction of substance lost by reason of congenital post-infectious or posttraumatic defects, or following the excision of a malignant tumor represents one of the most difficult problems in plastic surgery. An abnormal ear is conspicuous and an absent one is a major cephalic deformity. Criteria for successful reconstruction have been set down by Suraci who lists seven points as essentials if the reconstruction is to be acceptable to the patient and to the surgeon. These are: correct size, similarity of outline, similarity of height, correct cephaloauricular angle, permanency of size and shape, rigidity, and matching color.

The general principles of the technique of Pierce who reported 4 cases in which he used fine cartilage as an inlay graft combined with a cervical tubed pedicle to construct the helix, have been followed with agreement in execution with the advancements of Brown and others. In several cases subtotal reconstruction of the ear has been carried out in two stages. The management of cases included in this report has led to the opinion that suitable reconstruction of the external ear can be accomplished if sufficient attention is given to the cutting and the carving of costal cartilage to the importance of the establishment of a lateral concavity to represent a concha and to the many minor details which enter into the execution of this type of reconstructive surgery.

Experience in the handling of fresh costal cartilage has led to observations which have contributed to success in obtaining a suitable restoration of the external ear. A common objection to the use of straight grafts of cartilage in reconstructive surgery is that after transplantation the graft may undergo distortion of shape, curling. The use of a gouge causes compression of medullary and cortical cells of the costal cartilage in such a way that even after carving, the graft tends to warp or curl. The use of two scalpels prevents abnormal compression of cells and minimizes this tendency. In order to obtain a large graft two adjacent rib cartilages are resected en bloc. The excision of a disc, 2 to 3 mm in thickness at the level of each transection makes easier the removal of such a block of cartilage. Inspection of such a graft from its posterior aspect shows that there is a concavity in the cartilaginous portion of the thoracic cage. This can be used effectively in the carving of cartilage for reconstruction of the ear. As the rib cartilage is split longitudinally advantage is taken of the curling effect to exaggerate this concavity. Cartilaginous or fibromuscular fusion of two adjacent cartilages is made use of in obtaining the desired width of graft. With attention to these details it is possible to cut and carve from costochondral cartilage a free graft which has size, shape and rigidity suitable for reconstruction of the external ear.

Ten cases are reported in which partial or complete reconstruction of the external ear has been carried out. Reconstructions have been effected by the use of buried free grafts of cartilage, their elevation from the head and their backing by free grafts of skin at a second operation. A small tubed pedicle has been used to effect the appearance of the helix in some cases. Technical details in the cutting and carving of costal cartilages have been set down.

The opinion is advanced that reconstruction of the external ear acceptable to both patient and surgeon can be effected if attention is given to these details.

JOHN F. DELPER, M.D.

Problems of Diagnosis in Obstruction of the Eustachian Tube. FALKENBERG T. HILL. *A. M. Otol Rhinol* 94:5, 57-543

The author believes there are four main causes of obstruction of the eustachian tube: (1) nasopharyngeal lymphoid hyperplasia, (2) acute upper respiratory infection, (3) malocclusion of the bite with resulting compression of the tube, and (4) the possibility of a nasopharyngeal tumor.

Three cases of tumors and one case of a luteal lesion of the torus tubaris, which led to obstruction of the eustachian tube, are reported.

JOHN J. BALLEWORE, M.D.

Clinical Record—Gradenigo's Syndrome, with Report of 2 Cases. S. HOROWITZ. *J. Laryngol.* 94:8, 63-639.

The author discusses Gradenigo's syndrome—its incidence, clinical manifestations, x-ray appearance, etiology, pathology, and treatment.

The syndrome usually occurs during childhood and adolescence, although no age group is exempt, and the majority of cases are in males. The right ear is slightly more affected than the left.

The syndrome is characterized by three outstanding symptoms: (1) suppurative of the middle ear, (2) intense pain, usually intermittent over one or more branches of the fifth cranial nerve, and (3) loss of function of the external rectus muscle. In most cases the pain is intermittent, rather severe, worse at night and occurs mainly over the temporoparietal region although commonly in back of the eyes. The distribution varies, and the fibers of the gasserian ganglion mainly are affected. Anesthesia of the cornea may occur. Some patients may complain of pain on motion of the eye. The most outstanding symptom is paresis or paralysis of the sixth cranial nerve usually on the side affected but occasionally on the contralateral side or more rarely on both sides. The third, fourth, seventh, or eighth nerves have occasionally been involved. Paralysis of the abducens nerve leads to symptoms of diplopia. It is observed in the late stages of mastoiditis and is uncommon in the early stages. The average time is from 10 to 40 days after the onset of the ear infection.

If appropriate treatment is carried out, normal function is restored in from 2 to 4 months, but occasionally it takes as long as 6 months. Frequently

nystagmus may accompany the paralysis and occasionally the patient complains of photophobia. The temperature may be normal, but more often it is between 100 and 102 degrees, and in some cases as high as 104 or 105 degrees.

The x-ray appearance is indicative of the condition of the mastoid and the petrous apex. Positive findings are helpful but negative findings do not exclude a pathologic process.

The disease begins in the middle ear and the infection passes to the petrous apex by the continuity of cells, or by direct bone extension. The sixth nerve is affected in the apex of the pyramid when the dura is swollen from the infection with resulting pressure on the nerve. The disease may also be complicated by a localized meningitis and extradural brain abscess, or by an extension of thrombosis from the lateral sinus up to the inferior petrosal sinus. Petrous invasion is more common in the pneumatized temporal bones because the infection can more readily enter the petrous apex by advancing along this cellular structure. There are two main routes of cells extending to the petrous tip—the "antrum-epitympanic" route and the "hypotympanic" route. The organisms involved in the process are usually the pneumococci and streptococci but almost any organism can cause the disease.

The prognosis of the disease depends upon the treatment that is given, the accessibility of drainage, and the duration of the disease. The mortality varies from a per cent to as high as 50 per cent, but with the use of sulfonamides and antibiotics, it is hoped that the prognosis may improve.

With regard to treatment, the author states that on rare occasions cure may take place spontaneously but at times the syndrome may terminate in generalized meningitis and death. Surgical intervention with operation on the mastoid is usually required in order to obtain favorable results, occasionally myringotomy suffices. About 80 per cent of patients will recover after simple mastoidectomy but radical mastoidectomy and even petrosectomy is necessary at times. The use of sulfonamides and antibiotics will assist further in effecting a favorable outcome.

The author presents reports of a case of Gradenigo's syndrome. One case was that of a child, aged 14, with acute mastoiditis and lateral sinus thrombosis. This child also developed an otitic hydrocephalus. The second case was that of a 30 year old woman who developed Gradenigo's syndrome in the typical manner from a highly pneumatized mastoid and petrous bone. Following radical mastoidectomy supplemented by antibiotic therapy both patients made a complete recovery.

WILLIAM A. AMBROOK, M.D.

The Functions of the Round Window. ERNEST GLEY, WEAVER and MERLE LAWRENCE. *Ann. Otol. Rhinol.* 94:8, 57-579.

The authors present a study of function of the round window. Immobilization was accomplished in various ways while the electrical potentials of the

cochlea were recorded in order to evaluate claims of improved hearing resulting from surgical treatment by the use of round window grafts.

Fourteen cat ears with a ventromedial approach to the auditory bulla were used in the experiments. The cochlear potentials were recorded by an electrode placed on the round window membrane and this system was calibrated with the amplifying system to show the magnitude of the response in absolute units. The authors procedure was to measure the response of the ear to a series of tones under standard conditions with (1) the round window free (2) the round window blocked by one of several agents and (3) with the block removed. The results from blocking were expressed as differences in decibels. The experiments were divided into 4 series.

Series 1 Immobilization of the round window membrane was accomplished by manual application of a nonconducting thin-shanked lucite probe in contact with the central half of the membrane's surface and producing a noticeable indentation. Not the slightest effect was seen upon the response of the ear to a continuing sound.

Series 2 Occlusion of the round window by an air tight pressure tube with the other end open to the air reduced the response to high tones slightly as measured in 3 cats. The reduction in response began around 500 cycles and increased regularly as the frequency rose to a maximum loss of around 10 decibels at 10,000 cycles.

With the tube held in the same position and an introduction of air pressure up to 25 mm of mercury the reduction in response noted was similar to that caused by the simple application of the tube.

Series 3 The third method of immobilization was by a bone wax pack pressed in place by a mechanically held lucite obturator. The authors believed that the responses suffered a small general impairment varying with frequency from 1 or 2 decibels at lower frequencies to 4 or 5 decibels at higher frequencies.

To test the possibility that the tube or obturator was interfering with the sound field, the lucite obturator was placed in its usual position without actual contact and no response was observed.

Series 4 In this experiment the lateral wall of the tympanic cavity with the drum and ossicles was removed and the sound tube with acoustic probe was sealed over the oval window so stimuli could be delivered directly to this site. After blocking the round window with wax there was little change in response to high tones but in some ears there was a reduced response to low tones although the exact amount in decibels was not stated by the authors.

From these experiments the authors formulate the following conclusions as to the nature of the mechanical change resulting from blocking the round window.

In the presence of the middle ear loading the round window adds mass to the responsive system whereas, in the absence of the middle ear the same treatment of the round window adds stiffness to the

responsive system. Furthermore the authors suppose that the middle ear contributes greatly to the stiffness of the cochlear system and less significantly to its mass this supposition being consistent with a previous study showing that removal of the middle ear affects most seriously the high tones.

In conclusion the authors state that there is no warrant for the use of an immobilizing procedure in clinical practice since the introduction of grafts into the round window can be of no benefit to hearing.

EUGENE L. DERLACKI, M.D.

Electrocoagulation of the Membranous Labyrinth Experimental Histological Studies in the Monkey LEROY A. SCHALL and J. H. TOM RAMBO *Ann Otol Rhinol* 1948, 57: 590.

The authors report their conclusions from histological studies of 7 ears in 5 monkeys operated on according to Day's procedure of coagulating the membranous labyrinth through a trephine opening in the lateral semicircular canal.

The stated purpose of the experimental studies was to demonstrate the histological changes occurring as a result of coagulation of the membranous labyrinth and to determine if possible, any variation of technique which might improve the prognosis for hearing.

Two of the ears were not included in the reported findings because of postoperative labyrinthitis caused by unintentional surgical accidents providing an avenue of infection.

The remaining 5 ears were classified according to the amount of current used and the postoperative date of sacrifice, as follows:

	Dial setting	No. Post-operative days
1	20	10
2	20	30
3	20	40
4	10	30
5	30	30

In the 4 ears in which the coagulating current with a dial setting of 20 or more was applied the membranous labyrinth was completely destroyed and the healing of the labyrinth occurred by fibrosis with progressive changes to bone formation. In the ear with the current reduced to a dial setting of 10 the only finding was incomplete destruction of the utricle and saccule. Thus the authors felt with the use of optimum current, complete and predictable damage to the membranous labyrinth results, and elimination of vertigo in Meniere's disease could be expected as a uniform result.

On the other hand the essayists found that there was no predictable correlation in the amount of damage to the cochlea resulting from a variation either in the amount of coagulating current used or the time elapsed since the operation. In 1 ear there was no damage to the cochlea. In the remaining 4 ears the damage varied from localized injury to the organ of Corti and the spiral ligament immediately adjacent to the vestibule (in 1 case) to varying degrees of exudate in the lymphatic spaces and atro-

phy of the functional elements. With the unpredictable cochlear damage, the authors believed that retention of serviceable hearing following operation by Day's procedure was improbable.

EUGENE L. DERLACKI, M.D.

The Radical Mastoid Operation. A. AMERSON. *J. Laryngol.* 1948, 68, 638.

The author presents a preoperative and postoperative audiometric statistical survey of hearing loss in chronic otitis media. The study is based on 535 ears examined clinically and audiometrically in the course of ear consultations for a Medical Board. The stated purpose of this presentation is to demonstrate in a statistical survey that the otologist may venture an opinion by otoscopy alone of the hearing loss in decibels within an insignificant limit of error in cases of chronic otitis media, without any interrogation or testing of the patient, or knowledge of the past history.

The statistical survey is an analysis of the hearing in 478 ears with chronic otitis media under the following headings: (1) 55 ears with a radical mastoid cavity (2) 31 ears with a cortical (simple) mastoid operation (3) 153 ears with chronic otitis media with granulations and/or cholesteatoma, (4) 38 ears with aural polyps (5) 30 ears with attic disease (6) 14 ears with subacute otitis media (7) 103 ears with active or healed otitis media, with a residual permanent perforation of the tympanic membrane and (8) 66 dry ears with the tympanic membrane healed.

All of these ears were tested by the audiometer whispered and conversational voice, and the audiometer.

The hearing of patients in each of these classifications was shown in composite audiographs, apparently an average of all the ears in each group.

Group 1. Thirty-seven ears, those with a radical mastoid cavity averaged in the composite audiograph. Apparently these cases which have been classified as demonstrating a complete loss of hearing are averaged at a 90 decibel loss. The audiograph showed loss averages of 50 to 60 decibels for frequencies up to 2048 and 60 to 80 decibels for the higher frequencies.

Group 2. Twenty-one ears on which a cortical mastoid operation had been performed. In this grouping in which hearing in the other ear was normal, the average impairment is 25 decibels for frequencies up to 2048, and 25 to 45 decibels for the higher frequencies. Where the other ear showed permanent defective hearing and the tympanic membrane on the operated ear showed an attic scar the hearing loss was 40 to 50 decibels for frequencies up to 2048 and 50 to 70 decibels for higher frequencies.

Group 3. One hundred and fifty-three cases of chronic otitis media with granulations and/or cholesteatoma. The average hearing loss is 40 to 45 decibels for frequencies up to 2048 and 50 to 60 decibels for the higher frequencies.

Group 4. Thirty-eight ears with aural polyps showed an average loss of 50 to 55 decibels for fre-

quencies up to 2048 and 60 to 80 decibels for the higher frequencies.

Group 5. Thirty ears with disease confined to the attic region. The composite audiograph shows a uniform loss of hearing of 25 to 30 decibels up to 2048 above which it varies from 25 to 65 decibels in increasing progression.

Group 6. Fourteen ears with subacute otitis media. The hearing loss averaged 20 to 25 decibels up to 2048 and 30 to 35 decibels for the higher frequencies.

Group 7. One hundred and two ears with active or healed otitis media with a residual permanent perforation of the tympanic membrane. The average loss was 25 to 30 decibels for frequencies up to 2048 and progressively from 30 to 50 decibels in the higher frequencies. This entire group was divided in several ways according to size of perforation and presence of moisture. Conclusions were that the ear which is discharging has a greater hearing loss, not usually exceeding 5 decibels, than when the ear is dry and the hearing loss is more marked for the large central perforation by an average 5 to 10 decibels.

Group 8. Sixty-six ears with healed tympanic membrane. The average loss was 20 decibels for the frequencies up to 2048, and 30 to 50 above this.

In addition, the author presents a composite audiograph of 44 ears with otitis externa. The hearing is almost within normal limits except for a high tone loss attributed to secretions in the ear.

NOSE AND SINUSES

Tumors of the Nose and Sinuses. LE ROY A. SCHALL. *J. Am. Med. Ass.* 1948, 37, 73.

During the past 16 years from 1930 to 1945 inclusive, a total of 219 patients with malignant disease of either the nose or the nasal accessory sinuses, or of both, were seen at the Massachusetts Eye and Ear Infirmary, Boston.

A recent survey reveals that among these 219 patients there were 139 males and 80 females. Their average age was 56 years, the youngest patient being 16 and the oldest 83 years of age. Ten of these 219 cases were untraced and 68 (30 per cent) showed a 5 year or longer survival.

The relation of the treatment to the survival rate may be summarized as follows:

Primarily surgical treatment. 5 year survival in 133
Primarily radiation treatment. 5 year survival in 72
Primarily radium therapy. 5 year survival in 10

The successful treatment of cancer of the nose and nasal accessory sinuses, as of cancer elsewhere depends largely upon early diagnosis, prompt and thorough treatment, and treatment that is neither too little nor too late.

The symptoms which may lead one to suspect cancer of this area are few in number and can easily be listed: (1) hemorrhage, (2) nasal obstruction, (3) referred pain to the teeth, (4) painless swelling, (5) paresthesia or anesthesia of the cheek, and (6) exophthalmos.

When a new growth is limited to the nasal cavity nasal obstruction and hemorrhage are the most frequent symptoms. A small growth of the anaplastic type with thin walled blood vessels may show early ulceration with subsequent hemorrhage as its first symptom. With the increase in size of the growth, nasal obstruction occurs. This obstruction is usually unilateral hence it is an axiom that any unilateral obstruction by a growth should be considered malignant until the microscope proves it otherwise. When the tumor is of the slowly growing variety with well developed connective tissue and thick walled blood vessels, hemorrhage may not occur and the only early symptom is that of nasal obstruction. The growth may have the appearance of a simple nasal polyp yet on its removal the hemorrhage may be excessive and this is suggestive of cancer.

The study shows that patients treated primarily by surgery, supplemented by external radiation, or radiation by means of radium in the operative cavity have a better than a 2 to 1 chance of a 5 year survival than those treated primarily by radiation.

JOHN F. DELPH, M.D.

MOUTH

Recurrent Epithelioma of Lip PERCIVAL P. COLE,
Brit J Surg 1948, 36, 79.

The author reports the case of a stoker aged 28, who was referred as a prisoner of war from the Royal Herbert Hospital. In 1939, he had cut the right side of his lower lip while shaving and an ulcer formed which did not heal. The man was treated with radium irradiation in Belfast.

In October 1941 two years after treatment, a recurrence was noted and in March 1942 he was admitted to the Royal Herbert Hospital. A biopsy taken there showed the growth to be an epithelioma. Wassermann and Kahn reactions were negative.

At this time the author observed a deep ulcer with raised edges, measuring 1 cm. by 1.5 cm. extending just to the mucocutaneous junction and involving the lower lip and a corresponding area of the angle of the mouth. There was considerable surrounding induration but no fixation to bone. The right submaxillary gland was enlarged.

The adopted method of reconstruction makes impracticable the approach to the anterior triangle by the usual incisions. The somewhat irregular line tracing the incision along the lower border of the jaw at the base of the anterior triangle divides the area of operation into two parts. In the lower part is the anterior triangle with apex downwards. Free access to its contents is obtained by the reflection of skin flaps posteriorly and anteriorly from an incision joining its apex below to a point roughly midway along its base above.

Operation was performed on May 2, 1942. Gas and oxygen were administered by intubation. The lower area was isolated from the face and mouth and a block dissection undertaken.

Adequate exposure was obtained without removal of the sternomastoid and the jugular vein so that, in this particular case the technique of Butlin was employed in preference to that of Crile. After clearance of the area the skin flaps were united by suture with dependent drainage at the lower angle of the wound. Following isolation of the area thus dealt with the malignant ulcer with a wide margin of surrounding tissue comprising the whole thickness of lip and adjoining cheek, was excised.

It is essential for success in this direction that the mucous membrane be defined and sufficiently freed to be dealt with as a separate layer. Incision of this layer upward and forward increases the length of the lower border of the mucosal flap and so permits it to reach to the midline, if necessary there to secure mucosal closure by suture to the corresponding layer of lip or to a corresponding flap from the other side if the whole lip has been removed.

This method of treatment, first reported in *Lancet*, 1920, 2, 845 has been adopted as the standard technique for reconstruction of the lower lip. It is believed to be the best method for cases in which the lesion involves the angle of the mouth and encroaches upon the cheek to a limited extent. For obvious reasons direct borrowing should be preferred to remote transfer of tissue in such cases but the choice can only be made after a careful survey of conditions present in the individual case.

In conclusion the author states that epithelioma of the lip is encountered most frequently after the age of 50 years. Its occurrence at the unusually early age of 28 in the author's experience was associated with a breach of surface occasioned by a wound or burn. War wounds by bullet or shrapnel have been responsible factors in several such cases, and it is noteworthy that malignancy supervened a very short time after their infliction. The same rapidity of onset is demonstrated in the present case.

Whatever the view that may be taken of the mode of treatment to be adopted for a primary lesion the author believes that recurrence after irradiation computed to be adequate is unquestionably an indication for surgical intervention. In this connection the surgeon would do well to remember the pernicious behavior of tissues in which permanent obliterated vascular changes have resulted from irradiation. In order to secure normal behavior and to eliminate as a preliminary to success a factor whose effect cannot be assessed or compensated for, it is advisable to remove the whole area subjected to irradiation as was possible in the present case.

The possibility of failure and the resulting compulsory resort to surgery constitutes a strong argument in favor of methods which secure intensive localized irradiation in preference to those which employ irradiation on a more diffuse scale. It is indeed a question whether initially the surgical approach should not be preferred to the radiotherapeutic approach. The article is accompanied by 5 figures and 4 photographs.

NECK

Trial Classification of Malignant Thyroid Tumors
(Essai de classification des tumeurs thyroïdiennes malignes) JOSEPH F. MARTIN, M. DARGENT and P. GOUTIER. *Ann. Path. Par.* 947: 7306.

Clinical experience demonstrates the value of distinguishing between cancers with a structure recalling more or less the original thyroid structure and cancers which have kept nothing of the normal type of thyroid structure; therefore the authors have used the classical criterion of tissular atypism, but for general reasons have preferred to adopt the orthoplastic, anaplastic and metaplastic qualifications. However the surprising mimetism of the thyroid cell does not allow this simple distinction to include the great variety of neoformations, and various groups must be individualized, especially in orthoplastic cancer. Each of them is easily defined by its histologic characters, but it is advisable not to attach absolute importance to the differentiation of these secondary morphologic and cytologic types, since mixed tumors may be seen with the characters of two or three variants on the same slide or in different fragments. However the histologic tests which define the orthoplastic, metaplastic, and anaplastic forms are strict enough to make it possible to put each tumor in its proper place. The proposed classification is as follows:

1. Epithelial tumors

Orthoplastic forms may be observed as (1) vesicular epithelioma with conservation of the cellular grouping into vesicles but malignancy is revealed by pleiomorphism, rupture of the basal layer, and cellular changes; (2) papillary epithelioma with arborescent proliferations centered on a connective tissue axis inside each vesicle and (3) trabecular

epithelioma (a) trabeculo-vesicular epithelioma with small dark cells (proliferating struma of Langhans), (b) epithelioma with large eosinophilic cells and (c) epithelioma with clear cells.

b. Anaplastic forms characterized by structural anarchy and cellular indifferentiation with frequent monstruities. There are nearly always necrotic zones. The more or less marked stroma reaction allows persistence of large groups of cells or insinuates itself between the neoplastic elements to wall them off in varying manners.

c. Metaplastic forms: (1) epidermoid type Herrenschildt's cancer and (2) connective tissue type touching the question of epithelioma.

2. Connective tissue tumors. They are rare: (1) fibrosarcoma, (2) lymphosarcoma and plasmocytosarcoma and (3) reticuloendothelial tumors: reticulosarcoma, histiocytosarcoma and hemangioendothelioma.

In some cases it is possible to see phenomena of differentiation of the fundamental substance with skeletogenous metaplasia of the stroma.

It might be astonishing not to find in this enumeration the so-called metastatic adenoma. This is really a slightly peculiar symptomatic form which, through strict clinical and histologic analysis, can usually be referred to a definite type of cancer such as tumor of the aberrant thyroid, cancer with slow evolution, or cancer with a very localized histologic onset. The few cases in which this does not apply are solved by the notion of latent and adenomatous epithelioma, a form in which the malignant hyperplasia is masked under vesicular or trabecular adenomatous conditions. It is in such cases that the malignancy tests acquire their full value (spreading beyond the capsule and vascular invasion).

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

A Method of Contrasting Visualization of Brain Abscesses (Ueber eine Methode zur Kontrastdarstellung von Hirnabscessen) HANZ KOLMA. *Chirurg* 1948, 19 247

The author suggests the roentgenological visualization of brain abscesses by puncturing them and injecting uroselectan (similar to diodrast) into them. This procedure is either preceded or followed by encephalography or ventriculography.

The author claims that this method would be of help in evaluating the position and the size of the abscess its relation to the ventricle and the cortex and in determining its operative approach.

SPINAL CORD AND ITS COVERINGS

Lumbar Herniations of the Nucleus Pulposus. An Analysis of 196 Operated Cases. E.S. GURDJIAN and JOHN E. WEAVER. *Am J Surg* 1948, 76 235

The authors' report is based upon a study of 196 patients seen in the 6 year period from 1940 to 1946 and having as their main complaint low back pain with sciatic radiation. All of the patients were operated upon and an analysis of the underlying pathologic changes is presented.

A single ruptured or protruded disc was found in 146 patients. Two herniated discs were found at separate interspaces in 9 patients—usually at the fourth and the fifth lumbar interspaces. Eight patients had a massive rupture of the disc. A calcified disc was found in 5 patients. In 28 of the patients no disc protrusion could be seen. A study of the 28 patients without disc protrusion revealed the underlying condition to be varicosities of the outgoing nerve root in 12 cases, root compression by continuous tissue in 7 cases, and herniation of a cauda equina filament through a dural opening in 1 case. No disc protrusion could be made out in 8 cases. The varicosities were thought to be typical epidural hemangiomatous tissue.

The spinal fluid was examined in all cases, and in the majority a slight elevation of the total protein to about 50 mgm. per cent was revealed. In only 4 cases was it above 100 mgm. per cent however it is not mentioned whether this pertained to the proved cases of herniated disc or included some of the other cases with unverified pathologic changes.

Mylography was carried out on 31 patients. An error of 25 per cent to 30 per cent was found including both the false positive and the false negative. Nevertheless it is felt that myelography is worth while, particularly in doubtful cases, in order to rule out the possibility of either multiple lesions or a neoplasm.

X-ray examination is considered an important adjunct in the diagnosis to rule out the presence of either sacroiliac arthritis, spondylolisthesis, lumbar spinal arthritis, Marie Strumpell disease, metastatic lesions of the lumbar spine, tuberculosis or sacral chordoma. The authors however emphasize that a ruptured or protruded disc may coexist with spinal arthritis, sacroiliac arthritis, iliac osteitis and spondylolisthesis. A narrowed intervertebral space does not necessarily indicate the level of a ruptured disc.

The pathologic changes of the intervertebral discs were divided into the following four categories: (1) a bulge or protrusion of the nucleus through a weakened but intact portion of the posterior longitudinal ligament; (2) a rupture of the nucleus through a tear in the annulus and the posterior longitudinal ligament; (3) a degenerating nucleus and annulus fibrosis causing reflex pain but not being associated with an actual protrusion of the disc; (4) rupture of the nucleus into the bodies of the adjacent vertebrae resulting in the commonly known Schmorl's nodes.

The symptomatology may be quite variable and may or may not be associated with neurologic signs. The main complaint is low back pain with radiation of pain down the sciatic distribution. The pain is usually aggravated by coughing, sneezing or straining at stool, however occasionally this aggravation of pain may not be present. Oftentimes the back ache precedes the sciatic pain by months or years but again they may have a simultaneous onset and occasionally may have only the sciatic pain. The examination usually elicits pain on straight leg raising. Pain may be aggravated by compression of the neck veins or by forward flexion of the head and neck, and by bending backward or toward the lesion. Percussion at the level of the lesion usually produces typical radiation of pain. The knee jerk may be lost with a disc at the third interspace. A disc at the fourth interspace may result in weakness of the extensor hallucis longus and hypalgesia along the lateral aspect of the leg and over the big toe. A disc at the fifth interspace is frequently associated with a diminished or absent ankle jerk and a mild sensory deficit along the lateral three toes and the corresponding portion of the foot. Severe neurologic signs such as foot drop, saddle anesthesia, and sphincter disturbances are associated with massive ruptured discs at either the fourth or fifth interspace.

The operative procedure usually consists of a partial hemilaminectomy with excision of the ligamentum flavum and the ruptured disc with curettement of the interspace. In patients with severe neurologic disturbances a bilateral laminectomy is usually performed. The fourth and fifth interspaces are routinely inspected in all cases. A spinal fusion was performed by an orthopedic colleague in 28 cases by the use of a massive tibial graft. The decision to perform a spinal fusion was based upon the presence of

a spondylolisthesis unstable fifth lumbar vertebra, or a long history of backaches. It is interesting to note that the fusion was usually performed only on one side—the side opposite to the removal of the disc.

The results of treatment were classified as follows: Excellent—a complete recovery good—marked improvement with ability of the patient to return to work fair—improved but with definite residual discomfort, and poor—unimproved and not able to work. Forty three per cent of the patients obtained excellent results, 25 per cent obtained good results, 30 per cent fair, and 12 per cent, poor results. An interesting and important finding is that the results in those cases in which operation was combined with a spinal fusion were apparently no better than those in which only a small hemilaminectomy with the removal of the disc had been done.

JACK I. WOOLY M.D.

PERIPHERAL NERVES

Causalgia Following Gunshot Injuries of Nerves.
JAMES C. WHITE, WILLIAM H. HENRY and EDWARD N. GOODMAN. *Ann. Surg.* 94:3, 8, 6

The authors discuss the clinical picture of causalgia, its etiology and treatment, and present the case histories of 13 patients observed in a Naval Hospital. In their opinion the term *causalgia* should be limited to include only the sequelae of penetrating wounds of the extremities which cause injury to the nerve trunks, and the triad of (1) burning pain in the hand or foot, (2) trophic changes in the skin, subcutaneous and bony structures and (3) autonomic phenomena such as excessive vasomotor and sudomotor activity. This syndrome occurred 13 times in some 400 patients with peripheral nerve wounds representing a rate of incidence of slightly over 3 per cent. In their case histories, the authors emphasize the immediate occurrence of symptoms in these patients after the injury the importance of thermal and emotional factors on aggravation of pain, and the effectiveness of adequate sympathectomy for its relief.

Although many aspects of the causalgic syndrome suggest that it is a form of psychoneurosis, the immediate relief of symptoms following proper surgical treatment indicates that the personality disturbance is a result rather than the cause of an endurable condition. The immediate occurrence of the syndrome after injury eliminates sepsis, ascending neuritis, anoxia, compression of the nerve by scar tissue, or the formation of a neuroma as etiologic factors. Injury to a major blood vessel was present in only 3 of 13 patients.

It was found that a quiet, warm environment, ingestion of alcohol, sleep, and febrile states increased the comfort of these patients. Questioning of the patients revealed that the burning pain and hyperesthesia were aggravated by cold, damp or very hot weather, cold air on the affected hand and loud or unexpected noises, annoying radio programs, jarring of the bed, excitement, harrowing movies or stirring

music, crying children, hypodermic injections into any part of the body arguments with other patients, physical exertion, defecation and urination, drinking anything cold, and laughing. The single common denominator which underlies these diverse irritants was a burst of sympathetic impulses emitted from the hypothalamus and causing vasomotor, pilo-motor and sudomotor responses in the hand and fingers, and in the toes and soles of the feet. These areas show the greatest evidence of autonomic activity and produce nervous sweating and vasoconstriction. There is no valid evidence that the sympathetic system plays any direct role in the central conduction of painful stimuli. It is, therefore, the authors' contention that the hyperesthetic state is caused and aggravated by autonomic impulses released at the hypothalamic level in response to thermal and psychic stimuli and distributed over efferent sympathetic neurones permitting a direct irritation of sensory afferent fibers at the site of nerve injury.

Total sympathetic denervation of a limb is an effective method for the relief of true causalgia. Failure in producing complete relief of pain is due to incomplete sympathetic denervation. It is emphasized that the area of denervation must reach well above the level of nerve injury. If there is temporary relief of pain following a diagnostic procaine block the patient should be operated upon at an early date before he has become dependent on narcotics, and especially before he has developed neurotic tendencies or irreversible atrophic changes in his bones and soft tissues. Preliminary neurolysis is totally ineffective and, if indicated, should be undertaken after the sympathectomy. Primary local surgery is recommended only if a foreign body is in contact with the nerve or when a septic focus is present.

In 4 patients a complete paralysis of a neighboring nerve trunk was also present after sympathectomy. Vasodilation was complete only in the area of intact peripheral nerve supply and the adjoining paralyzed areas remained cooler and somewhat cyanotic, possibly due to hypersensitivity of the denervated smooth muscles to sympathomimetic hormones. The paresthesias and milder hyperesthesias which accompany sensory nerve regeneration are not necessarily relieved by sympathectomy. These latter symptoms are mild and not influenced in any way by hypothalamic stimulation and increased sympathetic discharges.

GEORGE PERRET M.D.

The Role of Foreign Body Reaction in the Healing of Peripheral Nerve Injuries Due to Gunshot Wounds (Zur Frage der Heilung schussverletzter peripherer Nerven mit besonderer Berücksichtigung der Häufigkeit und Bedeutung der Fremdkörperperireaktion). EDWARD RANDEKATZ. *Chirurg.* 94:7 17-18; 1947

The author found that functional results were often poor following gunshot injuries of the periph-

eral nerves because of inflammatory processes and an increase in the amount of scar tissue resulting from foreign bodies. He studied the operative material obtained from 950 peripheral nerve lesions due to bullet or shrapnel wounds from 2 to 44 months after the injury. He found foreign objects imbedded in the nerve scar in 485 or 51 per cent, of the cases. Even after 20 months an active inflammatory process could be found around foreign material and scar tissue within the nerve segments. The most common foreign bodies were particles of clothing, plant fibers, wood splinters, earth particles and stone and bullet fragments. Oftentimes the foreign body reaction with increased production of scar tissue was caused by bandage or suture material. The foreign bodies were most frequently encountered in wounds produced by shrapnel fragments and were relatively rare in direct bullet wounds.

SYMPATHETIC NERVES

Temporary Interruption of the Sympathetic Impulses to the Head by Infiltration of the Cervical Sympathetic Trunk. HOMER D. KIRCH and ADRIAN F. REED. *Ann. Surg.* 1948 128: 101

The value of a transient interruption of the sympathetic impulses to the upper extremity and the head is now well recognized both therapeutically and in prognosticating the reaction to surgical interruption of these pathways. The more commonly accepted procedure of injecting or infiltrating about the cervicothoracic ganglion is a very satisfactory procedure and comparatively benign. However there are several potential complications which must be considered. These include the possibility of puncture of the apex of the lung, injury to the brachial plexus and puncture of the large vessels of the lower portion of the neck. In blocking the sympathetic impulses to the head a much simpler procedure would be to inject the sympathetic trunk at the level of the tuberosities of the fifth or sixth cervical transverse processes.

In order to elucidate this problem the authors performed a dissection of the sympathetic trunk on 33 cadavers. It was found that at the level of the fifth and sixth cervical vertebrae the sympathetic trunk lies on the longus colli muscle medial and

slightly anterior to the fibers of the scalenus anticus muscle, in a small compartment formed by a splitting of the prevertebral fascia. It is posteromedial to the carotid sheath and its contents. The constant relationship of the sympathetic trunk and its proximity to the easily palpated carotid tubercle and the anterior tuberosity of the transverse process of the fifth cervical vertebrae makes this a uniformly successful approach.

The technique advocated is to have the patient assume the supine position with the head flexed and turned slightly to the opposite side. This permits easier palpation of the tuberosities of the transverse processes of the fifth or sixth cervical vertebrae and permits easier retraction of the carotid sheath and its enclosed vessels medially. In a slender person a small hypodermic needle may be used throughout; however in a heavier individual a 21 gauge venous puncture needle will suffice. The needle is usually inserted along the posterior border of the sternocleidomastoid muscle (which is retracted medially with the carotid) and is then advanced until it is in contact with the lateral surface of the tip of the transverse process. After withdrawing it slightly it is reinserted along the anterior surface of the tuberosity. At a depth of approximately 5 cm. from the lateral extent of the transverse process the injection is performed. Although the possibility of entering the intervertebral foramen is extremely slight nevertheless it is mandatory that aspiration be performed before the solution is injected. The injection may be performed by retracting the sternocleidomastoid muscle and the carotid sheath laterally; however this produces more discomfort to the patient. A successful block is usually obtained after 3 to 5 c.c. of a 1 per cent solution of procaine hydrochloride has been injected, although it may be necessary to inject up to 8 or 10 c.c.

The authors have used this technique approximately 350 times with satisfactory results. There have been no significant sequelae; however a patient may complain of slight pain on insertion of the needle or hoarseness due to infiltration about the recurrent laryngeal nerve. Repeated injections, however, resulting in increased vascularity with hypertrophy of the lymphoid tissue, may slightly complicate a future surgical procedure on this portion of the sympathetic trunk. JACK I. WOOLF, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Breast Tumors with Local Malignancy Giant Fibroadenomas, So-called Phyllode Adenomas, and Recurring Adenomas (Les tumeurs du sein malignité locale fibro-adenomes géants, adenomes dits phyllodes et adenomes récidivants) P. SAINT M. DARGENT and A. MARCELOUT *Lyon chir* 948, 45* 504.

Eight cases of breast tumor are reported. The largest of the enucleated tumors weighed 2 700 gm. The rapid growth, skin ulceration, progressive enlargement during menstruation and pregnancy and frequent recurrences after extirpation—up to seven times in one case—in these cases simulated cancer. However the absence of regional adenopathy and of metastases in other organs, as well as the absence of cachexia, proved that the tumor was only of local malignancy not a true carcinoma or sarcoma. It is characteristic of these tumors that they reach a very large size one weighing 7 500 gm. being recorded.

Although carcinomatous degeneration of fibroadenomas is rare treatment with androgenic or estrogenic hormones may be dangerous and is contra indicated. WERNER M. SOLMITZ, M D

The Prognostic Significance of Early Diagnosis in Breast Cancer STOVARD KAAE. *Acta rec N Stockh* 948, pp 475

This study is based on 500 cases of breast cancer and Paget's disease of the nipple seen at the Radium Center in Copenhagen between June, 944 and December 1946. These were all verified histologically except one which was clinically unmistakable and the patient died with metastases.

There were 17 cases of Paget's disease of the nipple in 2 instances associated with a carcinoma. Two cases of sarcoma of the breast were seen. There were 5 cases of carcinoma of the male breast. Among the 476 other cases, there was 1 patient who had had a breast tumor for 46 years so the factor of delay could not be accurately appraised and she is excluded in the final analysis.

The author personally interrogated the subjects included in the statistical series. The cause of delay in seeking medical advice after recognizing signs or symptoms of breast cancer was essentially ignorance of the possible gravity of the situation or fear that an unfavorable diagnosis would be rendered upon examination. The delay in coming to adequate treatment was sometimes the patient's fault, but also at times due to lack of energetic action on the part of the examining physician.

The significance of such delay has long been recognized and can be appreciated in the accompanying table, which illustrates the relation between delay and operability and between delay and the stage of disease when appropriate treatment was actually instituted. In this table cases in stage I are those

TABLE 1—SHOWING THE RELATION BETWEEN DELAY AND OPERABILITY AND BETWEEN DELAY AND STAGE OF DISEASE WHEN TREATMENT WAS INSTITUTED

Delay	No of Cases	Technically operable	Radically operable technically operable	Cases in stage I in which radical treatment was instituted	All cases		
					Stage I	Stage II	Inoperable
		Per cent	Per cent	Per cent	Per cent	Per cent	Per cent
Weeks or less	84	100	93	59	59		
Weeks—Month	69	84	65	36	53	4	6
1—2 Months	9	89	87	8	43	46	
3— Months	40	77	77	40		46	3
Over Months	90	7	18	38	41	30	29
Total	473	89	81	3	44	4	5

without demonstrable axillary metastases and those in stage II are those with demonstrable axillary metastases.

The increase in cases in stage I occurring with a delay of over 12 months is presumed to be due to a greater number of slow-growing late metastasizing tumors in this group. The cause for nonoperative treatment in the technically operable group was either refusal by the patient, advanced age or severe intercurrent disease. Education is believed to have already produced results but the author concludes "What is gained prognostically by the patient seeking medical advice early ought not to be lost by failure to have the diagnosis established at once."

TRACHEA, LUNGS, AND PLEURA

Parietal Complications of Collapsed Therapy (Complications pariétales de la collapsothérapie) A. BIZ BOU R. GORRA, and L. MARCEAUX. *J fr méd chi thorac*, 1948, 30

Patients who have undergone thoracoplasties often suddenly develop a serious pleural complication followed by infection of the thoracic walls. This complication may occur a long time after the operation. According to some statistics as many as 30 per cent of such patients die of the complication.

The authors had the same experience in their practice until they began to use forced aspiration and at a time when penicillin was unknown.

They have been able to bring about cures by evacuating the pus with simple pleural punctures, with or without the insufflation of air or lavage, or without

producing an oleothorax. They report cases in which the patients were cured by these simple means.

Not all abscesses are due to tuberculosis. The septic abscesses respond well to the sulfa drugs and to the antibiotics. Three of the authors' patients were successfully treated with penicillin. All of these had a large abscess of the chest wall following thoracoplasty.

Tuberculous abscesses of the thoracic wall still constitute a grave complication of collapse therapy. They may remain localized for a long time but they often pursue a progressive course spreading according to gravity from above downward most often but at times backward if the patient is confined to bed. They may spread out from a pleurotomy opening following the intercostal spaces or even spread in the most diverse directions forming the most unexpected fistulous tracts. These tracts are capable of giving rise to suppurative mediastinitis, caseous mediastinal adenopathies, esophagopleural fistulas, ulceration of the great vessels (e.g. the subclavian artery), areas of costal osteitis (vertebral or sternal) and caseous pleurisy.

Whenever possible the abscess, even a very large one, should be removed *in toto*. After complete removal of the abscess plastic repair of the defect should be carried out. If one finds a fistulous tract at the bottom of the wound in the course of surgical intervention it should be thoroughly removed and the caseous area should be thoroughly cauterized. Treatment with penicillin should then be instituted.

In the case of multiple tracts in varied directions it may be impossible to remove them all even by total ablation. This is true particularly when the tracts extend into the scapula. The therapeutic result will be incomplete and followed by recurrence.

Before employing surgery one should always try the sulfa drugs or better penicillin. One will be surprised to see the abscesses promptly disappear.

When medical treatment has failed and forced aspiration has proved unsatisfactory a well planned surgical procedure is necessary.

BLACKWELL MARKHAM, M D

Pulmonary Decortication for Chronic Posttraumatic Hemothorax; Constricting Pleura (La décortication pulmonaire pour hémithorax post-traumatique chronique; pleure constrictive). A P NAYS. *Helv. chir. acta* 1943 13 390.

Chronic organizing hemothorax, infected hemothorax and hemothoracic empyema are dangerous posttraumatic sequelae. The time when these disorders were treated by mutilating thoracoplasties of the Schede-Estlander type is now gone. Decortication and total pulmonary mobilization alone allow satisfactory healing and nearly complete restitution of functional integrity. This operation which was already performed toward the end of the past century has been adopted and improved by the Anglo-American war surgeon. Modern decortication was performed for the first time by Burford in May 1943 and more than 1,500 operations have been done since

then with excellent results and a mortality below 2 per cent. However, this impressive result should not obscure the fact that decortication is a serious intervention which like any modern type of intrathoracic surgery requires definite conditions for its success.

Successful decortication in a few isolated cases of chronic or subacute purulent pleurisy has again demonstrated the importance of obliteration of the empty pleural space by re-expansion of the lung to avoid eventual pleural suppurative. This can be compared with the capital role played by immediate pleural obliteration after partial pulmonary resection. It is impossible to overemphasize the importance of re-expansion of the remaining pulmonary parenchyma to avoid postoperative empyema.

Some technical details are very important. The epipleural plane of cleavage must be established exactly to allow blunt dissection without tearing of the intact visceral pleura, and during dissection the pressure must be exercised toward the shell and not toward the pulmonary surface. A pulmonary segment or an entire lobe may be in exceptionally bad condition and pulmonary segmental resection or lobectomy may be necessary. The whole lung from apex to diaphragm on the mediastinal side and at the fissures must be liberated and the parietal surface of the diaphragm must also be decorticated and the costodiaphragmatic and cardiophrenic sinuses developed. This will allow circumferential re-expansion of the lung in all directions. In general decortication of the parietal pleura is not recommended because it causes hemorrhage which is difficult to stop. Several intercostal drains are used and connected to a strong and continuous aspiration apparatus. If there is no intra-pleural suppuration the drains are removed as soon as the lung adheres to the chest wall between the second and fifth days. Positive pressure respiration with an anesthesia apparatus during the first postoperative days is very useful. Penicillin given by the general route by aerosol inhalation and by intra-pleural irrigation offers valuable protection. Voluntary exercises of unilateral respiration, intense thoracic gymnastics and relatively early ambulation are essential factors in the recovery of patients with thoracic injury.

RICHARD KEMEL, M D

An Improved Method of Resection of Pulmonary Segments. RICHARD H. OYERHOLT, FRANCIS M. WOODS, and RYER H. BETTE. *J. Tho. & Surg.* 1948, 17 464.

The development of the concept of the lung as a segmental organ is briefly traced and the importance of preserving at operation the healthy portions of lung is emphasized. The technique developed by various other authors is described. Since the present authors found certain objectional features in these methods they evolved a technique to overcome them.

Each bronchopulmonary segment is provided with a bronchial and arterial supply and a venous return all of which are consistent in pattern. The artery, vein and bronchus form the segmental hilum. These

structures and the pleura covering the segment are the important elements binding one segment to its neighbor. The intersegmental surfaces within a lobe of lung are made up of a loose areolar plane. The arterial and bronchial supply does not, typically cross this intersegmental plane although a few venous channels may.

In segmental resection, the arterial and venous channels at the segmental hilum are divided accurately. The segmental bronchus is then isolated, clamped and divided proximal to the clamp. The stump is closed with interrupted sutures tied over the end. With traction on the distal stumps of the divided hilar elements, the segment in question is stripped from its neighbor. This maneuver is aided by digital or gauge dissection along the intersegmental plane. This line of demarcation is determined by differential inflation under increased intrabronchial pressure supplied by the anesthesiologist wherein the intact adjacent segment will freely aerate in contrast to the atelectatic segment undergoing resection. The pleura is finally divided when it is reached by this dissection.

No special treatment is required for the intersegmental plane since there will be no significant air leak if an accurate separation has been done. A few intersegmental veins may require ligation.

This method has been used in 70 segmental resections in various combinations. Fifty-nine resections were carried out on 50 patients for bronchiectasis and 11 were done for other indications. In the bronchiectatic group there were 6 additional total lobectomies. The patients ranged in age from 7 to 55 years. The nonbronchiectatic indications included tuberculosis, chronic lung abscess, pulmonary cyst, benign tumor and metastatic tumor.

The only death occurred as the result of a hemo-pericardium produced by perforation of the pulmonary artery by a stainless steel wire suture used to close the bronchus. This suture material is no longer used. There were empyemas in 23 per cent of the 50 patients resected. Reoperation because of persistent pneumothorax was required three times. The segmental surface was responsible for this situation in 2 instances and the bronchial stump once. Whereas the complications are greater than in total lobectomy the conservation of lung tissue is believed to compensate adequately for this. The end results have been entirely satisfactory.

The text is supplemented by many semidiagrammatic illustrations. **HIRSH T. LANGSTON, M.D.**

HEART AND PERICARDIUM

Dysphagia Lusoria: Right Sided Aortic Arch. W. A. MARR. *Guy's Hosp Rep Lond.*, 94, 96, 86.

The term dysphagia lusoria means dysphagia from a "sport" of nature and has been used to describe examples of pressure on the esophagus from a right aortic arch.

The location of the aortic arch on the right side is a rare congenital anomaly. Maude Abbott having

found only 14 examples in 1,000 cases of congenital heart disease. Three varieties have been described. In the first type, which is not common, the right fourth arch persists to form the aorta while the fourth left arch persists to form the left subclavian artery which passes across in front of the esophagus and trachea. The second variety is the most common. Here the right fourth arch persists to form the aortic arch with the right dorsal aortic root. The left fourth arch disappears or is represented by a fibrous band, but the left dorsal aortic root persists and is joined to the left pulmonary artery by the ductus arteriosus and gives origin to the left subclavian artery. Because this "persistent left root" is dorsal in position, the left subclavian artery arises posteriorly and does not lie in front of the esophagus and trachea. Through the attachment of the persistent left root to the ductus arteriosus and the left subclavian artery the "right" or definitive aorta is pulled to the left behind the esophagus. The esophagus is thus displaced forward and to the left, and its lumen partly occluded by pressure from the diverticulum.

The third variety which is very uncommon, is persistence of both the left and right fourth arches with both dorsal aortic roots so that the esophagus and trachea are enclosed in an arterial circle.

Symptoms from uncomplicated right aortic arch are unusual. When present they may be dysphagia, parenchyma in the left arm, or dyspnea. Symptoms are more severe in cases of double aorta.

The author describes the case of a 37 year old woman who was studied because of difficulty in swallowing. Roentgenological studies showed the esophagus to be pushed forward and to the left. The right border of the great vessels was unusually prominent and curved toward the right. On the left, in the position of the aortic knuckle was a triangular shadow which was taken to be the blind end of the dorsal remnant of the left aortic arch. Tomography showed a connection between the persistent left aortic root and the left pulmonary artery the ligamentum arteriosum. The interpretation is that this patient suffered from right-sided location of the aorta of the second type described. She was relieved of her symptoms by simple conservative measures without operation.

JAMES E. THOMPSON, M.D.

ESOPHAGUS AND MEDIASTINUM

The Surgical Treatment of Carcinoma of the Thoracic Esophagus. LYMAN A. BREWER, III, and FRANK S. DOLLEY. *Read J Surg*, 94, 56, 517.

This article is a report of 30 proved cases of carcinoma of the esophagus, in 23 of which thoracotomy was done. Twenty two of the cancers were located at, or just below, the arch of the aorta. Eight were just above the diaphragm. Diagnosis is made on the history of dysphagia, usually progressive but sometimes with periods of remission. Frequently there was regurgitation of food as well as loss of weight and strength. A clinical picture of starvation

is the outstanding physical finding. Roentgenological examination and esophagoscopy confirm the diagnosis. Pathologically, squamous cell carcinoma (65 to 95 per cent) and adenocarcinoma (5 to 30 per cent) are found. Approximately 20 per cent of these lesions are located in the upper third of the esophagus, 37 per cent in the middle third, and 42.8 per cent in the lower third. Local spread to adjacent organs and lymph node metastases are of prime importance. Lesions at the arch or above spread to the trachea, bronchi, aorta, and mediastinum. Lymphatic spread is to the mediastinal nodes primarily although the cervical nodes are sometimes involved. In association with some lesions in the midthoracic esophagus subdiaphragmatic lymph node metastases are seen. Thus a combined thoracoabdominal approach is advisable. The contraindication is definite evidence of extensive spread of the tumor most commonly to the mediastinum.

The author describes his method of preoperative preparation and several methods of treating these lesions. His technique consists of an S-shaped incision at the level of the fifth rib posteriorly and extending down to the seventh rib and on to the abdomen. The mediastinum is explored for metastases and evidence of inoperability and the diaphragm is operated upon after the phrenic nerve is crushed. The stomach is then freed care being taken with the main branch and anastomotic arches of the gastropiploic artery. The right gastric artery is identified and preserved. The remainder of the esophagus is then mobilized care being taken not to injure the thoracic duct. After novocain injection, the vagi are cut. For high anastomosis the esophagus is divided at the cardia. However in lower lesions a portion of the stomach may have to be removed. The esophagus is then pulled up behind and above the arch of the aorta. Open anastomosis between the esophagus and the stomach is done with a layer closure of interrupted fine silk sutures. The fundus is used for the anastomosis a ring 2 cm. in diameter being used. The anastomosis is reinforced by the gastrocolic omentum which had been previously saved. The Levine tube is kept proximal to the anastomosis. The stomach is tacked to the parietal pleura from the arch of the aorta to the diaphragm. The chest is closed with catheters inserted and "under water" closed drainage is used. The patient is allowed to swallow water after a period of about 48 hours.

The importance of postoperative thoracic complications is emphasized. Two of the patients in this series developed wound infection which responded

promptly to drainage. The 2 operative fatalities occurred following resection above the arch of the aorta. Both of the patients had arteriosclerotic heart disease and auricular fibrillation. In this series 23 of 30 were explored and only 9 or 36 per cent were subjected to resection. The authors point out that the risk of transthoracic laparotomy in properly prepared patients is very small. Recently they have used postoperative supravoltage roentgen therapy over the areas previously involved with cancer in cases of squamous cell carcinoma. It is too early to state whether or not this treatment will increase the length of cure following operation.

ROBERT E. FLOREN, M.D.

Esophageal Resection with Intrathoracic Esophagostomy for Carcinoma in the Middle Third of the Esophagus (Carcinoma do esôfago médio-torácico. Esofagotomia parcial e esôfagostomia intratorácica.) HAROLD A. RODRIGUES. *Rev. Brasil. Cir.* 1948 17 51

This is a very detailed case report of a 57 year-old white man whose presenting complaints were dysphagia and vomiting of 3 months duration. An obstructing lesion of the esophagus was found on roentgenographic examination. No biopsy was obtained. On May 20, 1948 an exploratory thoracotomy revealed an esophageal tumor 5 by 3 cm in size which was located 8 cm. above the diaphragm. The esophagus was resected. The stomach was mobilized and an esophagogastric anastomosis was performed just below the aortic arch. The chest was closed with drainage. The lesion was a squamous cell carcinoma. Regional nodes were removed along with the esophagus and these were found to contain metastasis. The patient survived the procedure without significant complications.

The author traces the development of the present day technique of management in carcinoma of the esophagus and points out that this was the first successful resection for a lesion in the midesophagus performed in Rio de Janeiro.

During the first 10 days after operation the patient was kept in a head-down position. This was thought to favor evacuation of the tracheobronchial secretions prevent the swallowing of pharyngeal secretions avoid pendant traction on the line of anastomosis, and improve the peripheral circulation. Mouth feeding was withheld for 10 days. The closed drainage tube from the pleura was removed on the eleventh day. A course of deep roentgen therapy was given to the mediastinum.

HIRAM T. LANGSTON, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Contribution to the Study of Strangulated Inguinopropertoneal Hernia (Contributo allo studio delle ernie inguinopropertoneali strozzate) *ANNALI DI CHIRURGIA E GINECOLOGIA* 948, 35: 3

The author reviews his experience with 3 cases of inguinopropertoneal hernias which are considered of rare occurrence and which represent 0.37 per cent of the hernias encountered at his clinic.

The characteristics of this type of hernia are presented. Such hernias may be composed of a single sac situated between the transversalis fascia and the peritoneum and always in the vicinity of the inguinal region or they may possess two sacs one external inguinal the other internal propertoneal. There are three varieties: (1) iliac, when the sac is lateral and superior to the inguinal ring and thus in the iliac fossa; (2) vesical, when the sac is situated medial to the ring and near the urinary bladder; (3) pelvic or obturator when the sac is situated between the peritoneum and the pelvic wall near the obturator foramen. When two sacs are present they may have a common abdominal opening or the openings may be distinctly separate although, usually, close together. The opening is usually surrounded by rigid fibrous tissue. The size of the sac varies from that of a small nut to that of a fetal head or larger. The contents may be small bowel and omentum, or omentum alone. The alterations following strangulation, are caused by the action of the ring, represented by the abdominal ostium.

Of the 3 hernias seen by the author 2 showed strangulation and one of these was treated by resection. In both cases the sac was first opened by a rectus incision. After the hernia was reduced and the internal ring closed a regular Bassini repair was resorted to in the case not requiring bowel resection. The third case was complicated by small bowel perforation and abscess formation. A resection was performed with excision of as much of the sac as possible. Three layers of suture were used. The abdominal wall was then closed in layers. After a stormy convalescence the patient recovered and was discharged a few days later (21 days after operation) he returned with a recurrence of obstructive symptoms. There were signs of wound infection and segmental dilatation of the bowel, which, with the presence of ova in the stool, was diagnosed as ascariasis. The patient was treated conservatively with local heat and anthelmintics with good results. He returned a month later with similar symptoms. Following local heat applications drainage was established and 2 large worms were found. Later fecal matter was discharged which when injected showed commination with the transverse colon. Healing occurred without surgery. In 25 days.

LUCIAN J. FORDUTTI, M.D.

The Value Derived from Utilizing the Component Parts of the Transversalis Fascia and Cooper's Ligament in the Repair of Large Indirect and Direct Inguinal Hernia. *DAN C. DONALD, SURGERY* 1948, 24: 662.

Recurrences following the standard (Bassini) operation for large oblique and direct hernias prompted the employment of an operation utilizing the component parts of the transversalis fascia and allied ligamentous structures in such cases. In 116 cases of large oblique recurrent, and direct hernias in which this procedure was employed, questionnaires sent to the patients showed that there has not been a single recurrence of hernia with all questionnaires answered except three which were returned as undelivered.

The pathology of all inguinal hernia is not the same. To obtain the maximum results in the operation for inguinal hernia, it is necessary to consider the pathologic changes that accompany the different types of hernias in the inguinal supportive tissues. Since the transversalis fascial support is not involved in the small oblique hernia, usually seen in children, the treatment consists simply of the removal and closure of the patent processus vaginalis (sac) down to the fold of the peritoneum, and closure of the internal abdominal ring as in the Bassini operation.

The chief pathologic features in large oblique and direct hernias are the giving way of the transversalis fascial support and varying degrees of dilatation of the internal abdominal ring. Operations for these hernias should be directed toward restoring these structures to a normal state.

Special emphasis is placed on the importance of including the iliopectic tract in the suture line for closure of the transversalis fascia, to maintain the lateral support of the fascia. In the oblique hernia, the dilated internal abdominal ring should be closed by identifying its arms and approximating them with interrupted sutures above the spermatic cord.

In the operative management care should be taken to maintain hemostasis, thus preventing hematoma and serum accumulation which might invite infection and weaken the tissue support, and to avoid unnecessary trauma of the tissues, including the nerve supply which might result in weakened muscles. The operative field should be cleared of areolar and adipose tissues and straggling muscle fibers, for good visualization and prevention of their incorporation in the suture line which would weaken ligamentous support. CHARLES BRADY, M.D.

GASTROINTESTINAL TRACT

The Gastric Mucosa after Vagotomy for Peptic Ulcer: A Gastroscopic Study. *LEONARD M. ASH, GASTROENTEROLOGY* 948, 11: 393.

In order to evaluate the effect of vagotomy on the gastric mucosa, 30 patients were studied gastroscop-

Fig 1

Fig 1 (Donald) The transversalis fascia in the inguinal region. Relationship of iliopectic tract, transversalis fascia, and femoral sheath is shown. Inguinal ligament and fascia lata have been cut and reflected. The transected muscular portions of the internal oblique and transversus abdominis muscles are reflected to show the lateral portion of the transversalis fascia as it is continuous with the femoral sheath below. The separation of the conjoint tendon into its component parts (the transversus abdominis and internal oblique muscles) is shown. Henle's ligament is an inferior lateral expansion of the enveloping fascia and tendon of the rectus muscle blending and continuous with the iliopectic tract and femoral sheath.

Fig 2 (Donald) First row of sutures. Three sutures are placed 1 to 2 cm. apart through Hesselbach's ligament and

Fig 2

Henle's ligament above, and Cooper's ligament and the lacunar ligament below including the medial part of the iliopectic tract. The third suture is the last one incorporating Cooper's ligament. The remaining sutures approximate Hesselbach's ligament to the iliopectic tract up to the level of the internal abdominal ring. In cases in which Hesselbach's ligament above is thin, the aponeurosis of the transversus abdominis muscle is included in the suture bite. In this drawing a vertical relaxing incision has been made in the part of the anterior rectus fascia posterior to the external oblique aponeurosis. The inguinal ligament is not shown. The two arms of the internal abdominal ring have been identified and brought into view with Allis clamps preparatory to their approximation with interrupted sutures above the spermatic cord.

The presence of a gastroenterostomy which functions well serves to protect the gastric mucosa from traumatic factors by permitting more rapid gastric emptying and by allowing the reflux of alkaline small bowel contents. This accounts for the relatively smaller incidence of gastritic changes in the cases in which a gastroenterostomy was done at the time of the vagotomy. SAMUEL KAHN, M.D.

Phlegmonous Gastritis of Staphylococcal Origin
Partial Gastrectomy Massive Sacral Echar
Caused by Postoperative Pyemia. Failure of Penicillin Therapy (Gastrite phlegmonuse à staphylocoques. Gastrectomie segmentaire. Echarre sacrée massive et rapide par pyohémie postopératoire. Échec de la pénicilliothérapie). R. JOYEUX
Mém Acad chir. Par 1948 74 412

The author reports the case of a woman 50 years of age who complained of neuralgic pains in the left subcostal region of 8 months duration. Towards the end of this period she developed fever. A large tender mass adherent to the thoracic wall was palpable. Laparotomy revealed that the mass consisted of a large abscess in the anterior stomach wall which was surrounded by adhesions involved the small omentum and the gastrosplenic ligament, and was closely fixed to the thoracic wall. The pus contained staphylococci. Treatment consisted of partial resection of the stomach.

Vagotomy produces definite gastritic changes in the gastric mucosa. These changes occurred in 75 per cent of patients with vagotomy alone and in almost 50 per cent of patients in whom gastroenterostomy was done at the time of vagotomy. The mucosal changes most commonly seen consisted of hypertrophic gastritis not limited to any portion of the stomach and frequently associated with superficial erosions. The vagotomy probably influences the development of gastritis through producing an alteration in the circulation, an altered secretion of mucin with dissociation of acid and mucin secretion, and an altered motility.

These changes perhaps reduce the resistance of the gastric mucosa to physical trauma. Thus the operation which primarily seeks to separate the gastric mucosa from psychic trauma makes it more susceptible to physical trauma.

It is impossible to correlate the changes seen with the degree of free acidity found after vagotomy, and it is not possible to correlate these changes with the insulin test. In patients who have undergone gastroenterostomy. In patients who had had vagotomy only the gastritic changes developed in spite of evidence (by means of the insulin test) that the vagotomy had been complete.

Postoperatively a large gangrenous slough developed rapidly in the region of the sacrum and the patient died 5 days after the operation in spite of continued penicillin therapy.

Abstractor's note. It should be mentioned that the dosage of penicillin (500,000 units daily) appears rather low in view of the severe condition.

WILHELM M. SCHULTZ, M.D.

Clinical Considerations of Massive Gastroduodenal Hemorrhages (Considerazioni cliniche sulle grandi emorragie gastroduodenali). ELIO PAVIERI and G. SARTORI. *Riv. internaz. dir. sc.* 948, 8 305.

The authors review the literature and analyze 43 cases of massive hemorrhage observed among 451 patients with peptic ulcer who were treated from 1934 to 1947 at the Surgical Clinic of Pisa.

They believe that treatment of the first attack of hemorrhage should follow a medical régime. One should resort to surgery only when the hemorrhage is profuse, repeated, and uncontrollable and only when from the history and clinical picture, and (better still) from previous radiologic examinations, one finds that he is dealing with hemorrhage from a calloused or penetrating ulcer.

From numerous and various experiences, the authors have formed two axioms: (1) rarely is the first hemorrhage mortal and (2) "repeated hemorrhage aggravates the prognosis."

When surgery is resorted to the procedure of choice is gastroduodenal resection which is well tolerated by the patient and offers the surest form of hemostasis. Gastroenterostomy cauterization and consecutive inversion of Balfour should be considered only rarely.

When, after repeated transfusions, there is no improvement in the cell count and hemoglobin within 24 to 48 hours, surgery is performed following a rapid and fitting preparation of the patient.

LUCIAN J. FRODDOTTI, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Anatomicopathologic and Functional Changes in the Biliary System Following Cholecystointroflexion (Modificazioni anatomicopatologiche e funzionali della vi. biliare in seguito alla colecistointroflexione). CARMELO SPANZARATO. *Polichinica* sez. chir. 948, 55 125.

The author attempts to simplify biliary surgery by trying to eliminate the cavity of the gall bladder without excising this organ. The procedure consists of exposing the fundal half of the gall bladder and placing a purse string suture about the middle. After this the fundus is invaginated and the suture tied. This is followed by a second suture inverting the gall bladder still further.

A brief review of the literature follows, with a description of the different methods of handling the gall bladder, including those of Loreta Mayo, and Thorek. Only one author J. Lambret, has used a

method similar to that used by the author. Lambret invaginated the fundus of the gall bladder for stasis and atony. His work differs in that he tries to reduce the size of the gall bladder whereas the author attempts to eliminate the cavity entirely.

The author has performed this operation on 8 dogs and describes each operation in detail. This includes the cholangiogram reports, the pressure readings of the different parts of the biliary system at a second operation, and the histologic study of sections from the gall bladder and liver.

The results obtained show that it is not possible to obliterate the cavity of the gall bladder entirely although it was reduced to as much as, and even less than 10 per cent of the original size. Moderate distention of the remaining gall bladder often occurred but in only 1 case was it appreciable enough so that it could be referred to as cholecytic regeneration as reported by Balcer and others.

The invaginated mucosa shows atrophic changes side by side with proliferative changes. The cause for this is not understood but the changes may represent an attempt at regeneration.

The remaining ducts undergo dilatation which, however, is not constant, and there is usually an increase in pressure. Oddi maintained that there was a primary period of atony lasting 1 month followed by hypertonicity of the sphincter when cholecystectomy was performed. The findings in these experiments, however, showed a normal hypotonic, or hypertonic status of the sphincter of Oddi during the first month.

The hepatic cells showed degenerative changes which diminished or were even absent as the time interval following operation increased.

LUCIAN J. FRODDOTTI, M.D.

Differential Diagnosis Between Medical and Surgical Jaundice by Laboratory Tests. H. A. POWERS and FREDERICK STEIGMANN. *Ann. Int. M.* 1948, 29, 460.

The first problem in the differential diagnosis of the jaundiced patient is the distinction between the presence or absence of liver cell damage, and of marked interference with the bile flow. In general, the patient with medical jaundice has impairment of liver cell function, the patient with surgical jaundice has marked interference with the bile flow.

The follow-up studies of a large number of patients with an established diagnosis of jaundice permits an evaluation of liver function tests indicative of liver cell damage. At least two of the tests should be positive, before the presence of liver cell damage can be established, since every one of the tests may yield biologically false results occasionally.

In 135 cases, a combination of the thymol turbidity test with either the cephalin-cholesterol flocculation or the albumin-globulin ratio permitted recognition of liver cell damage in two-thirds of the cases. A combination of the cephalin-cholesterol flocculation test with the albumin-globulin ratio permitted this in a slightly smaller number of cases. If two posi-

tive results in all three tests were accepted, 83 per cent of the cases were correctly classified. The addition of the cholesterol-cholesterol ratio i.e. at least two positive results in the four tests raised the percentage of correct diagnoses significantly. The results of urinary urobilinogen determination brom sulfalein retention and hippuric acid synthesis added only a few more cases. In the vast majority of cases therefore liver cell damage can be diagnosed by means of four tests: cephalin-cholesterol flocculation, thymol turbidity, albumin globulin ratio and cholesterol-cholesterol ratio. The thymol turbidity test reduces the number of other more complicated tests required to classify cases correctly.

One test denoting marked bile flow interference was considered sufficient to indicate that phenomenon. In one third of 134 cases absence of urinary urobilinogen was the only positive test. In combination with other tests this absence was demonstrated in two-thirds of the cases. Marked elevation of the serum alkaline phosphatase alone was found in a relatively small percentage. If one positive test in the determination of either urinary urobilinogen or of serum alkaline phosphatase or of both was used as a criterion almost all cases in this group were accounted for.

One is struck by the frequent concurrence of both liver cell damage and marked bile flow interference—in 34.7 per cent of the cases studied. The previously stated premise that in medical jaundice there is only liver cell damage, and that in surgical jaundice as a rule there is only marked bile flow interference is therefore incorrect in a significant number of cases. Of the medical cases 26.3 per cent were complicated by marked interference with the bile flow. Of the surgical cases 60 per cent were complicated by liver cell damage.

SAMUEL KAHN, M.D.

Acute Torsion of the Gall Bladder. FRANCIS A. HAINES and JOHN T. KANE. *Ann Surg* 1948 129: 253.

Acute torsion of the gall bladder is an entity which is seldom mentioned in American literature. It occurs predominantly in elderly people, particularly of the viscerotonic type. As late as 1946 only 76 cases had been reported. As would be expected torsion occurs in those cases in which the gall bladder is free and completely surrounded by peritoneum. The relation between torsion and the movement of normal peristalsis in the transverse colon is mentioned also. Loss of elasticity of supporting structures may be a factor; stones do not seem to be an associated complication. In most cases the onset is acute with sudden severe right upper quadrant pain which may radiate to the back. Vomiting is a frequent finding. The mass felt in more than half of the cases, is usually tender; jaundice is rarely present. Early temperature pulse and respiration are normal but later they may show a marked rise. "Symptoms of peritonitis appear when the gall bladder becomes gangrenous and perforates. In the differential diagnosis cholecystitis or cholelithiasis must be con-

sidered. Appendicitis, intestinal obstruction, twisted ovarian cyst and ruptured peptic ulcer must also be considered. Early surgery is the treatment of this condition.

The author presents the case of a 63 year old man who had a smooth pear-sized mass one inch above the umbilicus and to the right of the midline. This was exquisitely tender and rigidity was present. A diagnosis of ruptured ulcer was made and the patient was operated upon. A dark shining gall bladder, twisted at the neck to 360 degrees was removed.

ROBERT E. FLOERZ, M.D.

Operative Cholangiography (La cholangiographie opératoire). P. L. MIRIZZI (Cordoba, Argentine). *Lyon chir* 1948, 43: 385.

Operative cholangiography is accomplished by the injection of an opaque substance, usually lipiodol, into the gall bladder or the common duct. The author, in reviewing the results obtained during 15 years of experience with the method is convinced that the physiopathological state of the biliary tract can be determined with a great deal of certainty by the use of the method described.

Functional dyskinesia of the sphincter of Oddi as well as complete or partial stenosis at the terminal bile duct may be demonstrated by the pencil-shaped elongated and dilated appearance of the common duct. This condition is due to the relative or absolute obstruction at the sphincter.

Various congenital anomalies such as cysts or pseudocysts of the extrahepatic tract, postoperative biliary strictures and anatomic narrowing of the terminal common bile duct from pancreatitis not only can be identified as such but their location can be established as well. The method is especially useful in demonstrating overlooked common duct stones as the cause of postcholecystectomy syndromes.

ORVILLE F. CRIMM, M.D.

Hepatic Duct Syndrome (Síndrome del conducto hepático). PABLO L. MIRIZZI. *J internat chir* Bruxelles 1948, 8: 731.

Cholangiography performed at operation has confirmed the hypothesis of a contractile mechanism in the common hepatic duct where its presence had been suspected on anatomic grounds. Histology completes the demonstration by revealing the presence of small annular and corkscrew muscle bundles along the entire canal. This mechanism has a propulsive function in the excretion of bile with a phase of dilatation (diastole) and one of contraction (systole). It has also a protective role, the effect of which is clearly shown not only in the normal biliary passages but also in the dilated choledochus which in its terminal portion impedes more or less the free entrance of bile into the duodenum. Experimental studies and biliary pathology provide valid confirmatory evidence of the protective role played by the hepatic duct system and this protective function justifies the performance of choledochoduodenostomy in cases of partial or complete obstruction of

a permanent nature which would inevitably lead to the icteric syndrome cholangitis and hepatic insufficiency.

The hepatic duct syndrome which is characterized by stasis in the hepatic system is the result of a functional disturbance and of anatomic factors. The functional disturbance consists of a spastic condition of the hepatic duct. The anatomic factors may be a local scar, an abnormal vessel, a displaced Hartmann pouch, a calculus at the entrance of the gall bladder or an obstruction at the junction of the cystic and common bile ducts. A calculus is the most frequent causal factor.

The syndrome simulates the icteric picture of calculus in the common bile duct but the jaundice usually disappears spontaneously or after passage of duodenal tube. In exceptional cases it persists until operation.

Clinical evidence, cholangiography, bacteriology, and pathologic anatomy confirm the existence of a hepatic duct syndrome due to cholangitis without calculus. The facts observed support the pathogenic concept of a descending infection. The first manifestations of which are limited to the hepatic duct system. The same data suggest that certain painful sequelae of operations for cholelithiasis have their origin in unrecognized functional or anatomic factors connected with the hepatic duct mechanism.

During a laparotomy the surgeon should determine the functional and morphologic condition of the hepatic duct system in an attempt to reduce as far as possible the incidence of the painful sequelae of cholecystectomy. This can be done only by cholangiography during the operation.

RICHARD KEMPT, M.D.

Strictures of the Common Duct. WARREN H. C. LE, JOHN T. REYNOLDS, and CARL BREYER, JR. *J. Surg.* 94B, 3-33.

Operative trauma is the most common cause of common duct stricture. Sixty-five per cent of this series of 49 cases of stricture could be directly attributed to operative trauma.

The operative mishaps responsible for the trauma are excision of part of the common duct while it is under tension by traction on the gall bladder; ligation of all or part of the duct while ligating a bleeding vessel; damage to the duct during gastrectomy and damage during choledochotomy. Another cause of stricture is obliterative cholangitis which may be caused by a collection of bile overlying the common duct, a small abscess adjacent to the duct, large masses of ligated material around the duct or possibly pykrophlebitis. In 10 per cent of this series of cases stricture was caused by a chronic pancreatitis of the diffuse fibrosing type. There are other less common causes.

The authors list 13 measures to avoid operative trauma of the common duct, as follows:

1. Maintain carefulness, and refrain from hurry while dissecting structures near the common duct.

Obtain good exposure of the region about the common duct with a long incision. The incision may

be oblique, transverse or longitudinal, but should be of sufficient length to give adequate exposure.

3. Obtain adequate relaxation with the proper anesthetic. Either is an adequate anesthetic in obtaining this relaxation but cyclopropane and curare are likewise effective.

4. Isolate the junction of the common duct and the cystic duct before ligating the latter structure.

5. Ligate no artery until it is proved that it enters the gall bladder.

6. Ligate the cystic duct and artery separately.

7. Cut no structure until it is identified.

8. Ligate the cystic duct at least one-half inch from the common duct. This distance will protect the common duct and likewise prevent reformation of a bulbous tip.

9. Control hemorrhage by pressure with the index finger of the left hand in the foramen of Winslow against the thumb so the bleeding point can be controlled by compressing the hepatic artery. By gradual release of compression the bleeding point can be identified and caught accurately with an artery forceps.

10. If adhesions are dense around the common duct, start dissection at the fundus of the gall bladder and ligate the duct or ampulla high.

11. Eradicate gall bladder disease early before massive inflammation takes place.

12. Be familiar with the abnormal anatomy as well as the normal. The anatomy of the biliary tract is so varied that we can identify no position of the various structures as normal. Normal can only be considered a composite of those types most commonly observed.

Methods of repair are described, and they vary with the level and extent of the stricture.

Local strictures. In cases in which the hilus of the liver is not involved repair is performed by simple excision with end-to-end anastomosis. The suture line is supported by a "T" tube inserted at least one-half inch below the anastomosis.

Stricture of the distal end only may be repaired in several ways. Side-to-side anastomosis to the duodenum with the use of a longitudinal incision in the side of the common duct is favored by the authors. Another method is to transplant the end of the common duct into the duodenum.

Stricture of the proximal portion of the duct should be treated, if possible by mobilizing and anastomosing the distal end of the duct. If it can be found to the hilar duct.

Absence of the entire duct is the most difficult and the end results of repair are the poorest. The Roux Y arm of jejunum is superior to anastomosis of the duct to a functional loop of intestine.

The hilar duct, if not viable after dissection, may frequently be located by aspiration. The duct may then be opened by incising along the needle with a bistoury and enlarging the opening by blunt or sharp dissection. The duct may then be anastomosed to the arm of the jejunum over a vitallium tube, rubber tube, or catheter inserted up through the arm of

bowel into the hilar duct, the other end brought out through the abdominal wall

The authors recently have devised a new method of anastomosing the defunctioned arm of the jejunum to the hilar duct. It is in essence a jejunal graft which is formed by separating the serosa and muscularis from the mucosa for 2 to 3 cm at the distal end of the jejunal arm. The flaring end of the bell end of a catheter is cut off and anchored in the mucosal graft with several silk or cotton sutures. The resultant tubular graft of mucosa supported by the truncated cylinder of rubber tubing is inserted with the narrow end into the liver up to the bile duct and anchored with two silk sutures.

The results of 63 operations performed upon 49 patients are summarized. Among 38 patients with a Roux Y type of arm excellent results were obtained in 78 per cent. In 4 of these the new procedure was used, with good results in 3. Excision of local strictures produced excellent results in 86 per cent. The results with anastomosis from the hilar duct to the duodenum were excellent in 14 per cent, and fair in 28 per cent. Failure occurred in 58 per cent. Miscellaneous repairs were excellent in 60 per cent. Failure occurred in 40 per cent. The overall operative mortality was 6 per cent.

FREDERICK C. HOESEL, M D

Etiology of Acute Pancreatitis. ROLF LIUM and STEPHEN MADDOCK. *Surgery* 1948 24 593.

Experiments with the production of acute pancreatic inflammation and fat necrosis by tying the pancreatic ducts and stimulating the pancreas have been reported. Stimulation of the pancreas has been produced by (1) feeding (2) acetylcholine and eserine (3) pilocarpine (4) stimulation of the vagus and (5) secretin. In a high percentage of these experiments combining obstruction of the pancreatic ducts and stimulation of the gland acute inflammation of the pancreas and fat necrosis resulted. The most extensive and consistent damage resulted when the animals were fed 3 hours before ligation of the pancreatic ducts.

The different mechanisms that can produce obstruction of pancreatic secretion were discussed. The clinical and experimental evidence was correlated to explain the varying degree of acute pancreatitis seen at operation or at autopsy.

Acute pancreatitis is the result of ductal obstruction in an actively secreting pancreas.

Acute Abdominal Disease in the Aged. WILLIAM C. BECK. *Surg Clin. N America* 1948, 28 1361

Eight hundred and eighty two patients over the age of 65 were admitted to the Guthrie Clinic, Sayre, Pennsylvania during a 5 year period, with abdominal complaints. In 31 per cent of these the condition could be classified as acute. The diagnostic problem in elderly people with acute abdominal

Fig 1 (Cole, Reynolds, Ireneus) Repair of stricture of common duct by preparation of a mucosal tube and implantation as a graft into the duct opening at the hilus of the liver (modification of Hoeg operation). This procedure is most applicable when no stump of duct remains, and scarred liver tissue must be incised to reach the duct. Depth of the scarred area is exaggerated to better illustrate the method. The mucosal tube is pulled into position and held there by two sutures, each of which is inserted from the outside into the depth of the opening, through the mucosal sleeve, and back through the depth of the opening to the outside where the two ends of each suture are tied together.

disease is usually not the same as that in younger patients because of various factors.

Precious time is lost because families are often convinced that the older members must have aches and pains, and that age itself is such a deterring factor to surgery that it is practically hopeless to ask for surgical aid. As a result older people come into the hospital far later than a similar group of young people.

Cholecystitis with its complications is considered to be the most common acute abdominal disease in the aged, if cases of strangulated hernia are considered separately from those of strangulation from other causes. Over 60 per cent of all abdominal complaints in the aged however fall into these three diagnoses. Next in frequency is diverticulitis and its complications. Appendicitis and perforations, and other complications such as peptic ulcer, encountered so frequently in the young are the least common of the major acute diseases of the aged.

In the present series acute gall-bladder disease was recorded in a patient of 80 years. The pain is usually far more diffuse than in younger individuals and often is centered considerably lower in the abdomen than it is in the young. The pain does not radiate so characteristically to the scapular region and in some patients may radiate directly through to the region of the upper lumbar vertebrae. The tenderness of the abdomen is rarely well defined and localized, and the muscle guarding may be quite diffuse. Fever is often totally absent and the leucocyte count is also completely unreliable. The course of the acute process is possibly more fulminating in the older patient. Rupture of the gall bladder occurs with greater frequency and the patient is less apt to recover spontaneously.

Calculi in the common bile duct are as frequent in the aged as in people in middle life. It is the author's conclusion that patients of advanced age with acute gall-bladder disease should be given a trial of conservative therapy but with much closer and far more frequent observation than younger patients. Unfortunately one must rely almost entirely on clinical sense since laboratory aid is of little consequence. Operation is indicated unless the patient improves perceptibly under conservative treatment.

Subacute obstructions of the colon which are due to carcinomas of the bowel may often be relieved by conservative measures. On the other hand the complete obstructions require a decompressive procedure. In older patients colic is often not as severe as in the young, while distention may be tremendous. X-ray interpretation is somewhat more difficult since the ileocecal valve is more frequently incompetent.

The diagnosis of femoral hernia is frequently missed in the admitting room and it is usually not discovered until the patient is in the ward. Other causes of obstruction are more difficult to diagnose. Mesenteric thrombosis was diagnosed in two of three instances in this series and one patient was saved by massive bowel resection. The indications for surgical intervention are complete obstruction of the colon, strangulation obstruction, and irreducible hernia.

The operations were usually carried out under spinal anesthesia and in most instances this seemed to be ideal. Probably in no disease of the aged is the importance of adequate nutritional balance as necessary as in bowel obstructions. Full hydration, and protein and vitamin balance must be maintained parenterally. Repeated studies of the alkali reserve and of the urinary nitrogen excretion are of real value in guiding the therapy. Renal balance is often precarious, and the reserve low in the aged, so that salt retention may be a real problem.

The mortality in 34 cases of strangulated hernia was 11.76 per cent. Patients 88 years of age were operated upon successfully for hernia. The length of time that some of these aged patients have known of their hernias is remarkable. One patient in the author's series had worn a truss for 40 years.

Attempts at reduction by taxis are made first. This is attempted only if the pressure on the sac is not painful and if the patient has not had any reduction for a period of 4 hours. A hernial sac containing bloody fluid will usually be hard and tender and the patient will usually not permit taxis. Placing the patient in a Trendelenburg position for 15 minutes will often facilitate reduction. If this is unsuccessful, an emergency operation is performed. The anesthetic used for such operations consists of a combined anesthetic routine with a field or intersit block supplemented by pentothal or an inhalation medium in very small amounts. In the male with an inguinal hernia the author often removes the testis, thereby saving time and securing a simpler repair. Early ambulation is of benefit.

Colonic diverticulitis and its complications seem to have replaced appendicitis as a frequent cause of acute inflammatory disease of the abdomen in the aged. In all but one of 33 patients in this series the inflammatory lesion was situated in the area of the sigmoid colon. In 1 patient the lesion was in the cecum and had perforated.

The therapy of diverticulitis in the aged, like that in all age groups, is dependent upon the stage of the disease. Only for perforations with a diffuse spreading peritonitis is immediate operation necessary. This consists of exteriorization of the perforated segment, or a proximal colectomy. In patients with localized processes, conservative therapy is usually adequate. At present the author is using sulfacetamide and either sulfadiazine or combel. As soon as the acute process has subsided, sigmoidoscopic and roentgenographic techniques are employed for further diagnosis.

Only 8.8 per cent of the patients with acute abdominal distress had acute appendicitis. These patients had either gangrene of the appendix or a perforation, due more to the late arrival of the patient at the hospital than to the rapidity of the process. The oldest patient with acute appendicitis was 70 years of age. All patients subjected to operation survived.

Of the author's series of 7 cases of perforated peptic ulcer in patients over the age of 65, operation was performed on 6. All of these patients survived. The age of the oldest patient was 86. The diagnosis of perforated peptic ulcer in the aged is not much different than diagnosis in younger individuals. Operation consisted of a high right paramedian incision, and suture of the perforation with either catgut or cotton with the use of through-and-through sutures. Omentum was tied into the knot. Gastric suction was maintained for 48 hours and ambulation was started on the third day.

In no field of acute surgery is more judgment or tact necessary than in the aged. Many old people feel themselves beyond the age at which surgical intervention is possible, yet there is appreciable preservation of health which surgery can offer to patients within this group.

HAROLD LUTTMAN, M.D.

GYNECOLOGY

UTERUS

Contribution to the Study of the Association of Utero-Ovarian Neoplasms in Women with Uterine Fibromyomas (Contributo allo studio delle associazioni neoplastiche utero-ovariche in donne portatrici di fibro-miomi uterini) MARIO OROCHER. *Ann. ostet. ginec.* 1948 70 300.

The author gives an extensive bibliography concerning multiple tumor formation in general and the association of benign with malignant tumors in particular. However concurrent development of multiple tumors in the genital organs is relatively rare.

In a material consisting of 726 cases of fibromyomas the author encountered 3 cases of sarcoma of the uterus, 16 cases of carcinoma, 27 of serous ovarian cysts, 2 of parovarian cysts, 4 of tubo-ovarian cysts, 2 of ovarian fibromas, 3 of ovarian papillomas, and 1 case of carcinoma of the ovaries. Sarcoma of the uterus was present in 0.45 per cent and carcinoma of the uterus in 2.2 per cent of the entire material.

While some consider a simultaneous occurrence of two different tumors in the genital organs as pure coincidence, others believe that an intimate genetic relation exists between both tumors.

Numerous workers maintain that an ovarian hormone exerts its effect on the uterine muscles. In the presence of ovarian dysfunction such a hormone may represent an important factor in the development of a tumor.

Macroscopic and microscopic study of 3 cases of sarcoma associated with fibroma convinced the author that the malignant degeneration was not a primary process but followed the degeneration of fibrous nodes.

Possibly the coexistence of two different neoplasms may be due to one single factor.

As to the simultaneous occurrence of ovarian tumors and tumors of the uterus, the existence of a functional utero-ovarian synergism suggests that an abnormal stimulus of the fibromyoma may be responsible for the development of an ovarian tumor.

It is evident that a failure to disclose the presence of two different tumors in the same patient may be responsible for improper treatment.

JOSEPH K. NARAT, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Results of Operation for the Restoration of Tubal Patency (I risultati delle operazioni per il ripristino della pervietà tubarica) E. PASCA. *Ann. ostet. ginec.* 1948 70 328.

Occlusion of a tube may develop in its intramural portion, the isthmus, the ampulla, or in the region of the abdominal ostium. The occlusion may be of congenital origin, caused by a defect in the evolution of

Mueller's organ, or by an intrauterine inflammatory process. More frequently a tube becomes occluded following an infection by gonococci or colon or tubercle bacilli, and compression by a cyst or a neoplasm of an abdominal organ, bridges or adhesions caused by extrinsic processes such as appendicitis may also be the responsible factors.

The following operations have been suggested for restoration of the patency of an occluded tube: ovariopexy, salpingostomy with salpingo-stomatoplasty and resection of the uterine horn and the isthmus portion of the tube followed by implantation of the remaining part of the tube into the uterus.

Of 364 patients operated on for tubal occlusion 202 could be followed up.

In 52 a bilateral tubal resection, bilateral salpingostomy and stomatoplasty were performed. Pregnancy occurred after the operation in 9.6 per cent of this group.

In 110 patients a unilateral tubal resection with salpingostomy and stomatoplasty was performed and the other tube was preserved. In this group gestation followed the operation in 13.3 per cent of the cases.

In 9 cases resection of the tubal angle and implantation of the tubes were performed. The operation was done on one side in 1 patient and on both sides in 8 patients. In 44 per cent of this group pregnancy followed the operation.

Gestation was recorded in 20 per cent of the group of 5 patients in whom ovariopexy had been done.

In 17 or 8.4 per cent of the total group of 202 patients subjected to operation, gestation was recorded, but only in 6 was the gestation carried to full term.

An operative procedure for occlusion of a tube is indicated only if the patient is younger than 35 years, if there is no evidence of inflammatory changes in other parts of the genital tract, if there are no signs of infantilism, and if no disturbance of other organs associated with internal secretion are present.

JOSEPH K. NARAT, M.D.

EXTERNAL GENITALIA

The Influence of Gonadotropic Hormones on the Biology of the Vagina (Physiologie des Bases) (L'influence des hormones génitales sur la biologie du vagin, bases physiologiques) J. A. SCHOCKAERT and J. FÉRY. *Gyn. obst., Par.*, 1948 47 421.

Histologic and chemical studies of the vaginal epithelium provide valuable information on the action of sexual hormones. They enable the physician to form a correct judgment as to the hormonal equilibrium and by repeated examinations to control the effect of his treatment.

The following procedure should be followed (1) histologic examination of the vaginal epithelium (2) determination of glycogen content by carmalum stain by the Schiller test or by quantitative analysis (3) determination of the pH by colorimetric or electrometric methods (4) examination of the vaginal content either by smear or by aspiration (5) bacteriological studies.

Four types of cells from the epithelium are found. The first of these are so-called 'atrophic' cells from the deep layer of epithelium they are small, with large nuclei and basophil cytoplasm. The second are intermediary cells from the spinous layer these are larger oval or fusiform and basophil with intensely staining periphery. The third are superficial cells these are large squamous, polygonal, mostly with acidophil protoplasm and pyknotic nucleus. The fourth are acidophil cells without nucleus. The proportion of each of these types of cells varies in a characteristic way during the monthly cycle.

The authors describe in detail the histology and chemistry of the vaginal epithelium during fetal life in the newborn in the prepubertal period in the adult, in pregnancy in the puerperium and in the menopause. The production of estrogen determines the growth and differentiation of the epithelium in puberty and its involution at the climacteric.

The production of progesterone causes desquamation of the superficial layers, and other typical changes. It is, however difficult to determine the time of ovulation by a study of vaginal curettings.

The acid reaction of the vagina is caused by endocrine factors and not by the Doederlein bacillus. However experiments carried out during the prepubertal period show that the Doederlein bacillus produces considerable increase of acid ty.

WERNER M. SOLMITZ, M.D.

The Influence of Gonadotropic Hormones on the Biology of the Vagina. Pathology and Therapy (L'influence des hormones gónitales sur la biologie d la vagin, pathologie et thérapeutique) IL D. WATTEVILLE and L. DAMON *Gyn. obs. Par.* 1945, 47, 437.

An insufficient or excessive output of sexual hormones changes the histologic structure of the vagina its glycogen content, its pH, and its bacterial flora in typical way. For this reason various affections of the vagina can be treated successfully with gonadotropic hormones.

Low estrogen output causes atrophy of the epithelium and a decrease of glycogen content. The consequent diminution of acidity favors the development of a pathogenic flora. Thus, atrophic vaginitis and in the most severe cases, kraurosis may develop. The vagina becomes more susceptible to mechanical, chemical or infectious lesions.

Estrogen treatment is indicated not only in atrophic vaginitis of adults but also in vaginitis of the prepubertal period and in vaginal hypoplasia.

On the other hand an abnormal increase of estrogen may cause hyperemia, leucorrhea and an in-

crease of acidity and may lead to the development of mycoses. Abnormally high acidity may also be a cause of sterility.

Increased progesterone production, as in pregnancy causes venous hyperemia softening of the mucosa and transudation.

The administration of testosterone causes atrophy of the vaginal epithelium with a decrease in glycogen and acidity. It is indicated in conditions of abnormally high estrogen production.

WERNER M. SOLMITZ, M.D.

Fibromyomas of the Vagina (I fibromiomi della vagina) LIVIO DE VELLATI. *A. n. del gi.* 1945, 70, 35.

Two cases of fibromyoma of the vagina in middle-aged married women are reported. One patient had never been pregnant, the other had had 3 pregnancies and 1 normal childbirth. In the nullipara, the growth was silent and was discovered accidentally in the other woman there was some metrorrhagic bleeding which brought her to the gynecologist. In both of these patients the vaginal new growths were associated with a fibromatous uterus and the vaginal tumor was at first thought to be a subunguiform cervical fibroid.

In both instances a total hysterectomy was done, with removal of that part of the vaginal wall to which the tumor was adherent. Histologic examination then disclosed the fact that the pedicle took origin from the smooth vaginal musculature—from the right side of the vaginal fornix in one patient, and from the left in the other one. The histologic study of the tumors themselves showed that they were fibromas with a vast predominance of the fibrous elements, especially at a distance from the insertion of the pedicle. There was no evidence anywhere of epithelial glands, or centers of hyperplasia of muscular tissue which would support the theory of their origin from embryonic rests or from remnants of the Wolffian duct.

Despite the lack of evidence of dysembryogenesis, the author believes that these tumors arose from a disordered embryogenesis with remnants of the embryonic elements persisting until the ages of 40 and 45 years, respectively. At these ages there arose a proliferative moribigenic stimulus which, in the light of modern concepts, is envisaged as an augmentation in the production of folliculin, this augmentation taking the character of increase in quantity and also of increased duration (dysfolliculinism).

MISCELLANEOUS

Röntgen Diagnosis in Gynecology and Obstetrics (Roentgen Diagnostique en gynécologie et obstétrique. La radiodiagnostic en gynécologie) R. KELLER. *Gyn. obs. Par.* 1945, 47, 430.

The author gives an exhaustive report on the use of hysterosalpingography for diagnostic purposes.

The capacity of the normal uterine cavity does not surpass 2 to 3 c.c. but may be much greater in pathologic cases. It is important to use the manometer for measuring the tonus of the uterine musculature which is normally between 4 and 6 cm. Hg in the week following menstruation. In uterine hypotony it may drop to 2 or 3 cm. and in spastic dysmenorrhea it may be elevated up to 10 or 15 cm. In order to fill the tubes with contrast material a pressure of at least 10 cm. must be applied but it should never surpass 30 cm. Hg.

As to the different substances in use, the author believes that perabrodil initiated by Kjellberg of Sweden is superior to lipiodol or thorium salts. This watery solution is very liquid and passes through even very narrow tubes furthermore it has the advantage of mixing freely with liquid material as in hydrosalpinx or ovarian cysts. It can be used without risk in metrorrhagia, and as it diffuses readily to the circulation no danger of embolism is present. It is eliminated by the kidneys in from 0.5 to 2 hours. In contrast to this fast elimination of an aqueous solution lipiodol that has entered the free peritoneal cavity by way of the tubes disappears usually after 6 to 8 weeks however in fixed pockets and recesses it may stay for months or years.

The risk of hysterosalpingography is minimal if the procedure is performed technically correctly. Local reactions ("oil peritonitis") are extremely rare and seem to occur only when the amount of injected lipiodol is unduly large. In such cases local peritoneal irritation may give rise to adhesions. The only two contraindications are acute inflammatory processes and the possibility of pregnancy. The best time to perform the examination is between 5 and 7 days after menstruation.

The study of the evacuation of the contrast material by means of a series of films is important for the diagnosis of hypertony or hypotony of the uterus.

The clinical application of hysterosalpingography is manifold and helpful for the diagnosis of the majority of pathologic processes in the genital tract. Malformations and infantilism of the uterus, polyps and submucous tumors of benign or malignant character, retention of placental tissue and other pathologic conditions can be diagnosed with less risk and greater exactitude than by any other clinical method. In metrorrhagia of hormonal or other origin curettage is the method of choice but hysterosalpingography often gives valuable additional information if applied by the "thin layer" method which produces a well differentiated relief of the mucous surface. The same is true in pathology of the tube and ovary. Various types of salpingitis, hydrosalpinx, stenosis and occlusion of inflammatory or mechanic origin can be differentiated by this method.

However, the study of sterility has benefited from hysterosalpingography more than that of any other field in gynecology. It is no longer admissible to start the treatment of sterility without the informa-

tion given by this method. Not only the condition and permeability of the tubes but a number of other pathologic processes like malformations, uterine deviations, and cervical irritations may be the cause of sterility and can be discovered roentgenologically.

Finally pelvic tumors outside of the uterine cavity can be visualized by a combination of hysterosalpingography with pneumoperitoneum.

WERNER M. SOLMITZ, M.D.

Amenorrhea Among the Inmates of German Concentration Camps in 1944 and 1945 (L'amenorrea nelle internate nei campi di concentramento tedeschi, 1944-45) EMIL BLENYASZ. *Ann. ostet. gin.* 1948 70 371

Practically all female inmates of the concentration camp in Auschwitz were suffering from amenorrhea which lasted from 3 to 4 months.

The author ascribes this phenomenon to an inhibition of the neuroendocrine centers.

In instances in which the amenorrhea lasted more than 3 or 4 months other factors had to be considered. These cases could be divided into two groups: (1) the psychic, in which the causes were anguish, confusion and uncertainty and (2) the physical in which the causes were mainly inanition, hypovitaminosis and overwork.

JOSEPH K. NARAT, M.D.

The Cytology of Neoplasms of the Female Genital Apparatus, Before and After Radium Treatment, Studied by the Apposition Method (La citologia dei neoplasmi dell'apparato genitale femminile, prima e dopo trattamento radium studiato con il metodo della apposizione) MARIO BIANCHI. *Tumori, Milano* 1948 34 82

The impetus given to the interpretation and evaluation of the radiation changes to be observed in the normal and abnormal cells of the female genital tract by recent studies particularly those of Ruth M. Graham (*Surg. Gyn. Obst.* 1947 84 153 and 166) makes further examination of the subject seem desirable. The author's material included 45 cases of neoplasms of the female genitalia, consisting of 25 epitheliomas of the portio, 10 of the undifferentiated type, 3 spinocellular and 8 basocellular, 4 were undifferentiated carcinomas. There were also 3 adenocarcinomas of the cervical canal and 13 of the uterine corpus, 2 ovarian cancers, 1 chorioepithelioma and 1 primitive carcinoma of the vagina. In addition to the usual vaginal smear, serial biopsy and histologic methods, the author employed the method of apposition. This consisted in pressing the glass microscopic slide lightly against the area to be examined. When this slide is pulled away it brings away with it both neoplastic and normal cells and this specimen is then fixed with methyl alcohol, stained by the Giemsa method and examined just as is done in blood smears. The apposition method was also extended to the study of such normal tissues as the ovary, placenta and other tissues of human preg-

nancy and to the noninfiltrative type of chorionic mole.

The author does not state that his findings were essentially different from those reported by Graham but his purpose in making the study was not so much the solving of the question of prognosis and evaluating the efficacy of irradiation as apposed to surgery as the determining as to whether any one characteristic of the cells or any combination of characteristics of the single cell—irradiated or not—would establish a diagnosis between the normal and neoplastic cell in this region, or between the different types of neoplastic cell.

From the results of these studies it is concluded that no single characteristic of the cells and no combination of characteristics of a single cell in this material will establish a certain distinction between the neoplastic and the normal cell. It is true that a general consideration of all the characteristics of the different types will usually enable a distinction between the cell of carcinoma of the female genital tract and the normal cells of the same region, or between the neoplastic cell and the cell of other morbid conditions not neoplastic in nature. Even the individual response of these different types of cells to radiation treatment does not render the distinction more reliable. In general by the general consideration of all the characteristics of all the cells in a single patient studied, a distinction can be made between cancer and normal tissues or non-neoplastic morbid tissues however not even the response to irradiation will distinguish reliably the different types of carcinoma such as the epidermoid type and the adenocarcinoma. In the case of the chorionic cells not even the distinction between the neoplastic and non neoplastic forms can be reliably made. In other words the information to be gathered from a study of the cytology of the female genital tract is purely orientative in character and in such a sense it may be practically utilized.
